### Executive Summary

6 We propose a measurement of the beam-normal single-spin asymmetry  $A_n$  of the proton in  
7 the deep inelastic scattering (DIS) regime. We will use the electron beam of CEBAF, with the elec-  
8 tron spin polarized in the transverse direction, incident on a 40-cm long liquid hydrogen target.  
9 Scattered electrons will be detected in the SoLID spectrometer in Hall A of JLab in its PVDIS con-  
10 figuration, with scattering angle between  $\theta = (22^\circ, 35^\circ)$  and a full azimuthal angle ( $\phi$ ) coverage.  
11 By flipping the electron spin direction between (pointing) beam-left and beam-right or between  
12 vertical up and down, the beam-normal asymmetry  $A_n$  will be determined by the  $\phi$ -dependence  
13 of the measured asymmetry.

14 In the Born approximation, in which a single photon is exchanged, Single Spin Normal Asym-  
15 metries (SSNA) – with either the electron (BNSSA) or the hadron target (TNSSA) spin polarized  
16 transverse to the scattering plane – are strictly forbidden due to time-reversal and parity invariance.  
17 Going beyond the Born approximation, one finds non-zero SSNA due to two-photon exchange,  
18 and effects beyond the parton-model may enhance such asymmetry. Previous measurements of  
19 PVES in the elastic region showed large  $A_n$  asymmetry, but the 6 GeV PVDIS experiment at JLab  
20 revealed  $A_n$  in DIS to be consistent with zero albeit with large statistical uncertainty. Therefore,  
21 the proposed measurement will investigate, for the first time to a high precision, the effect of two-  
22 photon exchange in DIS via BNSSA and possible effects beyond the parton-model description that  
23 may enhance the asymmetry.

24 We request 38 PAC days of beam time that includes 4 days of commissioning and calibration  
25 or systematic studies and 4 days for the beam polarimetry measurement. The production beam  
26 time will utilize transversely polarized beam at  $70\mu\text{A}$  and includes 17 days at 6.6 GeV and 13 days  
27 at 11 GeV. By fitting the  $\phi$ -dependence of the measured asymmetry, we will reach a precision of  
28 a few parts per million (ppm) per each 1  $\text{GeV}^2$ -wide  $Q^2$  bin of DIS. If combining all  $Q^2$  bins, the  
29 combined precision on  $A_n$  can reach about  $\pm 2.1$  ppm for the 6.6 GeV and  $\pm 3.8$  ppm for the 11 GeV  
30 setting. Results from this measurement will provide the first high-precision test of two photon  
31 exchange calculation on BNSSA in the DIS region. If the asymmetry is enhanced by any effect  
32 beyond the parton model, we will be able to reveal it.

# 1 Introduction

## 1.1 Two Photon Exchange Physics

Our understanding and description of the internal structure of both nuclei and nucleons have seen a steady improvement over the past several decades. These improvements are sometimes brought on by inconsistent or unexplained experimental results, revealing limitations of our underlying assumptions. One such example is that of the discrepancy in the extraction of  $G_E^p/G_M^p$ , the ratio of the proton form factors of elastic scattering from either Rosenbluth or polarization transfer measurements at large  $Q^2$ , see e.g. [1] and references therein. At present, this discrepancy is attributed to two-photon exchange (TPE) and is used to quantify such effect [2].

With a focus on high precision measurements in future experiments, it is vital to expand on our understanding of these higher order processes. A renewed interest in interactions beyond the Born or single-photon exchange approximation has persisted, with a number of experiments over the recent years to study the effect, but most are focusing on the elastic regime. For example, comparison of electron vs. positron elastic scattering off the proton has been made at the VEPP-3 Storage Ring [3], using CLAS [4] at JLab, and by the OLYMPUS experiment at DESY [5]. Studies of TPE also form part of the main thrust of a potential positron program at JLab [6], with some ideas focusing on the use of small-acceptance spectrometers [7, 8, 9] while others using CLAS12 [10]. However, a precision comparison between electron and positron scattering has its own challenges with one of the main systematic uncertainties being the relative luminosity control between the two beams. For example, OLYMPUS reached a 0.36% uncertainty in the  $e^+$  vs.  $e^-$  relative luminosity difference, a significant accomplishment yet large compared with the expected size of TPE for the  $Q^2$  range of the experiment. The goal of the proposed measurement is to study TPE and other higher-order effects by measuring the beam-normal single-spin asymmetry to a high precision in the deep inelastic scattering (DIS) regime, and has different systematic uncertainties from experiments utilizing the positrons.

## 1.2 Single Spin Normal Asymmetry

One way that TPE effects have been investigated is through measurements of single spin asymmetries where either the lepton (incoming or outgoing) or the target spin is polarized normal to the scattering plane, i.e., polarized along  $\vec{k} \times \vec{k}'$  with  $\vec{k}$  and  $\vec{k}'$  the incoming and scattered electron's momentum, respectively. At the Born level, in which a single photon is exchanged, Single-Spin Normal Asymmetries (SSNAs) are forbidden due to time-reversal invariance as well as parity conservation [11]. Going beyond the Born approximation, SSNAs are no longer restricted and can provide direct access and insight into TPE effects. Figure 1 illustrates the single and two photon exchange processes, and the interference between their amplitudes results in the SSNAs.

There are two types of SSNAs that can be readily measured experimentally: Beam-Normal SSA (BNSSA) where the initial beam is polarized and the target is unpolarized, or Target-Normal SSA (TNSSA) where the beam is unpolarized and the target is polarized. SSNAs can also be studied by measuring the spin polarization of the scattered lepton or of the final-state hadronic system, but these are much harder to access experimentally and we do not discuss them here.

For electrons polarized normal to the scattering plane which interact with an unpolarized target, the BNSSA can be described as [12]:

$$A_n = \frac{\sigma^\uparrow - \sigma^\downarrow}{\sigma^\uparrow + \sigma^\downarrow} \propto \frac{\alpha_{em} m_e}{Q} \epsilon_{\gamma\delta\lambda\mu} S^\gamma P^\delta k^\lambda k'^\mu \quad (1)$$

Figure 1: Feynman diagram for one (left) and two (right) photon exchange processes. The single spin asymmetries are due to the interference between the two amplitudes.

111 where  $\sigma^\uparrow$  and  $\sigma^\downarrow$  refer to the cross sections of spin up and spin down electrons, respectively,  $m_e$  is  
 112 the mass of the electron,  $\epsilon_{\gamma\delta\lambda\mu}$  is the Levi-Civita tensor,  $S$  is the polarization vector of the incident  
 113 electron,  $P$  the four-momentum of the target, and  $k$  ( $k'$ ) the four-momentum of the incident (scat-  
 114 tered) electron. The expression  $\epsilon_{\gamma\delta\lambda\mu} S^\gamma P^\delta k^\lambda k'^\mu$  is strictly zero for beam with  $\vec{S}$  along  $\vec{k} \times \vec{k}'$  and no  
 115 BNSSA will occur, unless, a non-zero imaginary amplitude is present, which requires multi-photon  
 116 exchanges [13]. Stated more explicitly,

$$A_n \propto 2ImT_{2\gamma}T_{1\gamma}^*, \quad (2)$$

117 where  $T_{1\gamma(2\gamma)}$  is the one (two) photon exchange amplitude. BNSSA measurements can play an im-  
 118 portant role in our understanding of the TPE process because of their direct access to the imaginary  
 119 part of the TPE amplitude.

120 As a potential background to high precision Parity Violation Electron Scattering (PVES) mea-  
 121 surements,  $A_n$  were measured in experiments such as Qweak [14] for elastic scattering and the  
 122 6 GeV PVDIS experiment [15, 16] for DIS. However, the precision goal of these  $A_n$  measurements  
 123 was set by  $A_n$  continuation in the main PVES asymmetry observable, and typically only a day  
 124 of beam was dedicated to such measurement each time. One reason that a high precision, ded-  
 125 icated measurement of the BNSSA in DIS has not yet been performed is because of the use of  
 126 small-acceptance spectrometers. Combined with the very small size ( $\approx$  ppm) expected for the  
 127 asymmetry, it requires significant beam time to reach a meaningful precision for asymmetries in  
 128 DIS. A key feature of the proposed measurement is that the large acceptance of the Solid Large In-  
 129 tensity Device (SoLID) allows a high precision measurement of BNSSA in DIS within a reasonable  
 130 amount of beam time.

### 131 1.3 Existing SSNA Measurements

#### 132 1.3.1 Early BNSSA Measurements at SLAC

133 Interests in two-photon exchange originated as early as the first DIS experiment(s) at the Stan-  
 134 ford Linear Accelerator Center (SLAC). In a very early experiment [17], the ratio of  $e^+p$  and  $e^-p$   
 135 elastic-scattering cross sections was measured at  $Q^2$  values between 0.20 and 5.00 (GeV/c)<sup>2</sup>. The

136 measured ratio, after radiative corrections, are consistent with unity, with uncertainty ranging from  
 137  $\pm 0.016$  to  $\pm 0.123$ . These results gave the first limit for the size of TPE effects, but have rather large  
 138 uncertainties in the modern standard.

### 139 1.3.2 BNSSA Elastic Measurements

140 Measurements of BNSSA in elastic scattering were routinely conducted in PVES experiments as  
 141 part of the systematic effect study. With the realization that TPE may have a non-negligible ef-  
 142 fect in elastic form factor measurements, a number of experimental programs have measured the  
 143 BNSSA in elastic scattering for a number of nuclei over a variety of different kinematics. These  
 144 investigations have thus far shed some light onto kinematic and nuclear mass dependence of the  
 145 effect. Figure 2 is a compilation of the current BNSSA measurements for elastic scattering taken  
 146 at different experimental facilities, including data taken at both forward and backward angles. In  
 147 general, comparison between theory predictions and experimental data show a reasonable agree-  
 148 ment. However, a recent measurement at MAMI [18] shows a disagreement with available predic-  
 149 tions. These disagreements have been surmised to be due to missing intermediate states in theory  
 150 calculations and point to the need for further experimental and theoretical investigation to better  
 151 understand these discrepancies.

Figure 2: Compilation of existing elastic BNSSA measurements. Data from [18, 19, 20, 21, 22, 23, 24]

### 152 1.3.3 BNSSA DIS Measurements

153 At present, no robust, high-precision study of the BNSSA in DIS has been made. The only existing  
 154 data with ppm-level uncertainty are measurements made to estimate background in the JLab 6 GeV  
 155 PVDIS experiment [16], see Fig. 3. The uncertainty is large, and further exploration in the DIS  
 156 region with high precision is clearly desired. As suggested by Afanasev: “If we can measure this  
 157 to  $\pm 5$  ppm, it will be very useful information. Even  $\pm 10$  ppm is a big step, because pretty much  
 158 nothing is known for this in DIS” [25].

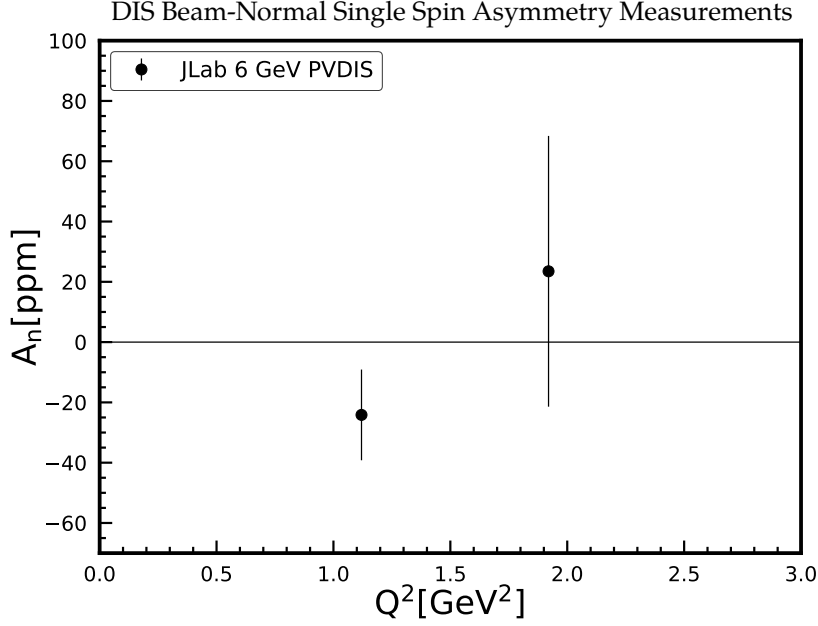

Figure 3: The DIS BNSSA for the deuteron, data from the JLab 6 GeV PVDIS experiment [16].

### 1.3.4 TNSSA Measurements

Similar to BNSSA, TNSSA also provides insight into TPE processes. Because the size of the asymmetry, depicted in Eq. (1), is proportional to the mass of the polarized particle of interest, TNSSA is expected to be much larger than BNSSA, making it relatively easy to measure. To study TNSSA, often denoted  $A_y$ , the target is polarized normal to the electron scattering plane with its spin direction flipped periodically, and the cross section asymmetry is formed between the two target spin directions. TNSSA was measured by several experiments. Most notably, TNSSA was measured at JLab using a polarized  $^3\text{He}$  target, used effectively as a polarized neutron target, for both DIS [26] and quasi-elastic scattering [27]. Figure 4 shows these neutron results and a clear evidence of non-zero TNSSA that is beyond the single parton-model prediction (see next section for details). On the other hand, similar experiments carried out at HERMES on a polarized hydrogen target [28] showed that the proton TNSSA is consistent with zero (within a  $10^{-3}$  level uncertainty) in the region  $0.007 < x < 0.9$  and two  $Q^2$  ranges of  $0.25 \text{ GeV}^2 < Q^2 < 1 \text{ GeV}^2$  and  $1 < Q^2 < 20 \text{ GeV}^2$ , and for both electron and positron beams. Clearly, further investigation in the TNSSA is desired and there is a plan to extend the measurement on both polarized proton and polarized  $^3\text{He}$  as part of the approved SOLID SIDIS program [29].

## 1.4 Theoretical Predictions for SSNA

At the present, the number of theoretical predictions for BNSSA in the DIS regime is limited. Parton model predictions exist with the assumption that the interactions occurs with a single quark, such that both photons of the TPE couple to a single quark in the target nucleon. Based on prior derivation for two point-like fermions[30], Metz et.al [12] have expressed the BNSSA for DIS as:

$$A_{TU} = \alpha \frac{m_e}{2Q} |S_T| \sin(\phi) \frac{y\sqrt{1-y} \sum_q e^3 q(x)}{[1 + (1-y)^2] \sum_q e^2 q(x)}, \quad (3)$$

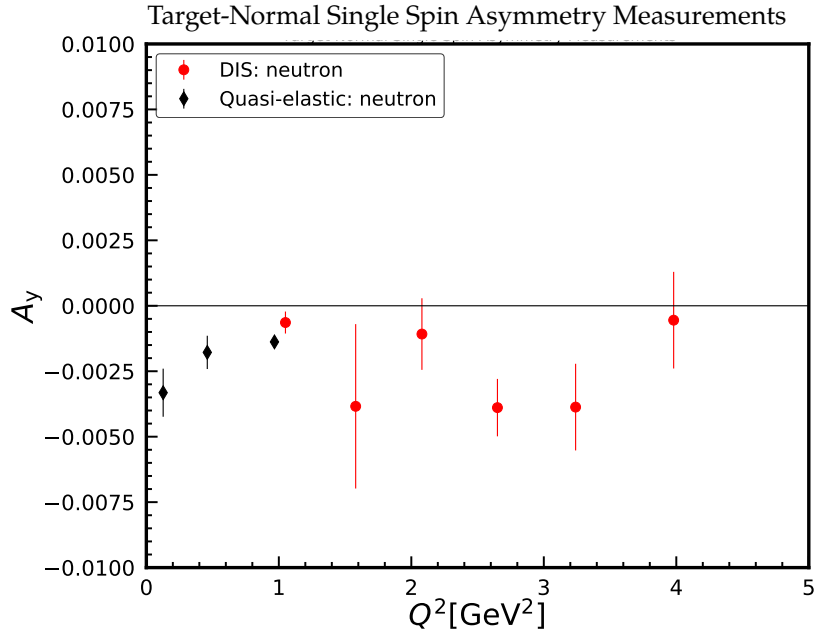

Figure 4: Target Normal Single Spin Asymmetry of the Neutron measured by JLab E07-013 [26] and E05-015 [27]

180 where  $\alpha$  is the fine-structure constant,  $m_e$  is the electron mass,  $S_T$  is the polarization of the electron,  
 181  $y$  is the fractional energy transfer, and  $q(x)$  are the parton distribution functions (PDFs) with the  
 182 relevant quark charge denoted as  $e_q$ . Similarly, Gorchtein et.al [31] calculated the BNSSA in elastic  
 183 scattering at very high  $Q^2$ , and provide an expression for BNSSA of an elementary fermion, from  
 184 which one can make an approximation to estimate the asymmetry in DIS. Both of these models give  
 185 predictions which estimate a BNSSA in the DIS region to be in the range between 0.6 - 6 ppm. En-  
 186 hancements to the BNSSA due to higher order effects, beyond those included in the parton model  
 187 calculations, would result in larger measured BNSSAs values [32]. While existing DIS data [16]  
 188 (see section 1.3.3) showed a hint that BNSSA may be at 10 ppm level, they have large uncertainties  
 189 and higher precision measurements are needed to establish non-zero, ppm-level values of BNSSA  
 190 in DIS.

191 The situation for TNSSA is different. Parton model calculation for the neutron, in which both  
 192 photons couple to a single quark, predicted an  $A_y^n \approx 10^{-4}$  [33]. On the other hand, considerations  
 193 in which the electron exchanges two photons with different quarks predict an enhancement of  $A_y^n$   
 194 to the level of  $10^{-2}$  [34], in good agreement with the JLab TNSSA data shown in Fig. 4.

195 Dedicated measurements focusing on TNSSA such as those planned as a run group experiment  
 196 with the SoLID SIDIS program [29], and those focusing on BNSSA such as the one proposed here,  
 197 would provide an important step in the understanding existing data, in constraining TPE models,  
 198 and in studying the validity of parton model in a variety of kinematic regimes.

## 199 2 Experimental Setup

### 200 2.1 Overview

201 We propose to measure the beam-normal single spin asymmetry in inclusive deep inelastic scat-  
 202 tering using a 40 cm liquid hydrogen target. We will measure the BNSSA using a 6.6 and 11 GeV

203 electron beam polarized in the horizontal direction and the beam spin is flipped between pointing  
 204 beam-left and beam-right following the helicity sequence (+ - -+ or - + +-). A luminosity on  
 205 the order of  $7.5 \times 10^{38} \text{ cm}^{-2}\text{s}^{-1}$  is expected for a 40 cm liquid hydrogen target and a  $70 \mu\text{A}$  beam cur-  
 206 rent. The scattered electrons will be detected using the PVDIS configuration of the SoLID detector.  
 207 The PVDIS configuration of SoLID with its baffle system has been designed and studied exten-  
 208 sively for the approved E12-10-007 experiment – “Precision Measurement of Parity-violation in  
 209 Deep Inelastic Scattering Over a Broad Kinematic Range” or simply referred to as “SoLID PVDIS”  
 210 or “PVDIS” [35] – and is particularly suitable for the proposed measurement.

211 Defining the electron beam direction to be  $\hat{z}$  and the unit vector  $\hat{y}$  pointing vertically up, and as-  
 212 suming that the beam spin is polarized in the horizontal ( $\hat{x}$ ) direction, the experimentally extracted  
 213 BNSSA can be expressed as:

$$A_{\perp} = \frac{1}{P_b} \cdot \frac{N^{\uparrow}(\phi) - N^{\downarrow}(\phi)}{N^{\uparrow}(\phi) + N^{\downarrow}(\phi)} = A_n \sin(\phi), \quad (4)$$

214 where  $P_b$  is the beam polarization,  $N^{\uparrow}$  and  $N^{\downarrow}$  refer to the charge normalized event counts detected  
 215 for the incoming electron spin pointing in the  $+\hat{x}$  (beam-left) and  $-\hat{x}$  (beam-right) directions,  
 216 respectively, and  $\phi$  is the azimuthal angle. By flipping the spin of the beam (spin left  $\leftrightarrow$  right),  
 217 we can measure  $A_n$  by analyzing the  $\phi$  dependence of the measured asymmetries. The transverse  
 218 beam polarization of the electron beam is expected to be  $P_b \approx 85\%$  for the proposed experiment.

## 219 2.2 Cryogenic Target System

220 The proposed experiment will use a 40-cm liquid hydrogen target, the same which is designed  
 221 for the PVDIS experiment [35]. Along with the cryogenic target, a dummy target mimicking the  
 222 cryo-target endcaps and additional solid targets will be included in the target system for calibration  
 223 purposes.

224 While the PVDIS experiment is expected to use a  $50 \mu\text{A}$  beam current, we expect that a  $70 \mu\text{A}$   
 225 beam current should pose no problem on the accelerator capacity [36] nor target cooling power. A  
 226  $70 \mu\text{A}$  beam on a 40-cm liquid hydrogen target will require 1.4 kW of cooling power, more modest  
 227 than the 2.5 kW of the Qweak target which was employed at JLab from 2010 to 2012. In addi-  
 228 tion, the MOLLER experiment will require a 5 kW ESR2, far exceeding the need of the proposed  
 229 measurement.

230 The liquid hydrogen and deuterium may become slightly polarized in the magnetic field of the  
 231 solenoid. This would result in an asymmetry unrelated to the physics of interest. In the case  
 232 of (ortho-)hydrogen, a 1.5 T field and 20 K temperature would result in a polarization of less  
 233 than  $10^{-4}$  along the direction of the field (longitudinal for SoLID). The use of pure para-hydrogen  
 234 would reduce this effect because para-hydrogen would not be polarized under high fields. At room  
 235 temperature, hydrogen is 25% para and 75% ortho. As temperature decreases, most ortho would  
 236 transition to para hydrogen, reaching a 99% pure para state within a week without the use of a  
 237 catalyst [37]. In the aid of a catalyst (such as the iron piping existing in the cryotarget system), the  
 238 ortho $\rightarrow$ para transition will be completed within a day [38]. We discuss quantitatively the effect of  
 239 target polarization on the measurement in Section 3.2.2.

240 Localized heating of the target from the electron beam can result in density fluctuation of the  
 241 cryogenic target, commonly referred to as target boiling. This effect can cause a reduction in the  
 242 density of the target as well as noise in the asymmetry that mimics the statistical uncertainty. To  
 243 minimize effects related to localized heating of the the target, the electron beam will be rastered  
 244 to  $4 \times 4 \text{ mm}^2$  with a square pattern. We note that specially designed cryogenic targets have been  
 245 utilized for high-precision PVES experiments at JLab, including Qweak. In addition, we expect a

246 dedicated target study to be carried out for the approved PVDIS experiment. We thus do not expect  
 247 target heating to be a significant contribution to the uncertainty of the proposed measurement.

248 The total thickness of the aluminum endcaps of the cryotarget cell will be approximately  $270\ \mu\text{m}$   
 249 ( $120\ \mu\text{m}$  upstream,  $150\ \mu\text{m}$  downstream). In order to account for possible background and dilution  
 250 from  $e^{-27}\text{Al}$  scattering, dedicated runs with an aluminum dummy target will be used to determine  
 251 the yield of the background. We take into account target endcap effect in our systematic study, see  
 252 Section 3.2.3.

### 253 2.3 The SoLID Spectrometer in its PVDIS Configuration

254 The proposed experiment will use the SoLID spectrometer [39], for which there are currently 5  
 255 approved experiments – on SIDIS, PVDIS, and  $J/\Psi$  production – along with an additional 6 run  
 256 group experiments, including measurement of TNSSA alongside SIDIS [29]. The SoLID spectrom-  
 257 eter is a large acceptance device which is capable of operating under a high radiation environment  
 258 and can handle high background and high rates. SoLID has two configurations: PVDIS and SIDIS,  
 259 allowing it to meet the broad experimental requirements of the SoLID program. The proposed  
 260 experiment plans to utilize SoLID in its PVDIS configuration, see Fig. 5. To handle the up to  $10^{39}$   
 261  $\text{cm}^{-2}\text{s}^{-1}$  luminosity, a baffle system is designed to greatly reduce the total background – in par-  
 262 ticular charge-neutral and low-energy charged background – in the detectors while reducing the  
 263 acceptance of DIS electrons by about a factor 3. The detector system of SoLID in the PVDIS con-  
 264 figuration consists of GEM trackers, light gas Cherenkov, and electromagnetic calorimeter, which we  
 265 describe in the next section in more detail.

Figure 5: Side view of the SoLID apparatus in the PVDIS configuration. For details see [39].

## 266 2.4 Detector System

### 267 2.4.1 GEM

268 Particle tracking for SoLID will be performed by Gas Electron Multiplier (GEM) trackers. The  
 269 GEM trackers are ideal for the SoLID detector due to the need for high resolution tracking coupled

270 with the high-rate environment over a large area. More specifically, we expect the GEMs to provide  
 271 a position resolution of  $70 \mu\text{m}$  with rates over  $100 \text{ MHz per cm}^2$  [39]. For the PVDIS configuration,  
 272 five layers of GEMs will be used, three before the light-gas Cherenkov and two after, see Table 1.  
 273 Each layer will consist of 30 sectors in the azimuthal direction, matching the baffle design. This  
 274 layout will allow for a 1 mrad polar angle and a 2% momentum resolutions.

Layer	$Z$ (cm)	$R_{min}$ (cm)	$R_{max}$ (cm)	Surface area ( $\text{m}^2$ )
1	157.5	51	118	3.6
2	185.5	62	136	4.6
3	190	65	140	4.8
4	306	111	221	11.5
5	315	115	228	12.2

Table 1: Location of the five GEM layers in the SoLID PVDIS configuration. The coordinate  $Z$  refers to the position along the beamline with target centered at  $z = 0$ , while  $R_{min,max}$  refer to the inner and outer radii of each layer.

### 275 2.4.2 Light Gas Cherenkov

276 A main component of the particle identification (PID) in the PVDIS configuration is the light gas  
 277 Cherenkov (LGC) detector. The LGC is comprised of an approximate 105 cm long radiator ( $z$ ),  
 278 with an inner (outer) diameter of 71 (85) cm and is divided into the 30 sectors, each consisting  
 279 of a pair of mirrors and one PMT onto which light is reflected [39]. The tank will be filled with  
 280 either  $\text{CO}_2$  or  $\text{N}_2$  gas. With the above design features, the LGC is expected to have a nominal pion  
 281 rejection on the order of  $10^3$  while maintaining an electron efficiency close to 95%.

### 282 2.4.3 Segmented Electromagnetic Calorimeter

283 The segmented electromagnetic calorimeter (ECal) consists of a preshower and a shower section.  
 284 The preshower configuration is that of a  $2X_0$  pre-radiator and a 2-cm thick scintillator. The shower  
 285 is a Shashlyk type sampling calorimeter with alternating layers of scintillator and lead absorber  
 286 with wave-length shifting fibers interleaved through the layers. The scintillation light is absorbed  
 287 and re-admitted by these wavelength shifting fibers and eventually captured by PMTs. The seg-  
 288 mentation of the calorimeter, at  $100 \text{ cm}^2$  in transverse size, was designed to best satisfy the require-  
 289 ments of the SoLID physics program, which includes the necessity of covering a large area as well  
 290 as operating in a high radiation environment. The specific characteristics of the calorimeter are  
 291 provided in Table 2.

	Performance
$\pi^-$ rejection	[50:1]
$e^-$ efficiency	90%
Energy resolution	$\delta E/E \leq 10\%/\sqrt{E}$
Position resolution	$\leq 1 \text{ cm}$
Radiation hardness	$> \sim 400 \text{ kRad}$

Table 2: Basic characteristics of the SoLID EM Calorimeter.

292 **2.4.4 Trigger and Data Acquisition System**

293 The proposed measurement will utilize the same trigger and DAQ system as the SoLID PVDIS  
 294 experiment. To keep the trigger rate at a manageable level, the detector electronics are divided into  
 295 30 sectors, each with a separate trigger. For each sector, the trigger will be a coincidence between  
 296 the LGC and the ECal with a 30 ns coincidence window. The current estimate of the DAQ limit  
 297 is 10 kHz per sector or 300 kHz total. This DAQ limit is the primary reason that we plan to use a  
 298  $70\mu\text{A}$  current at 6.6 GeV.

299 **2.5 Transversely Polarized Beam**

300 The electron beam at CEBAF is produced via photo-emission from circularly polarized laser in-  
 301 cident upon a GaAs photocathode [40]. The initial polarization of the beam is longitudinal and  
 302 then the orientation is manipulated by two Wien filters and a set of solenoids. The first Wien filter  
 303 rotates the spin to vertical and then the solenoid rotates the polarization to the horizontal plane  
 304 and perpendicular to the beam line (so called “flip-left” or “flip-right” setting). The second Wien  
 305 filter rotates the polarization about the vertical axis to the desired launch angle from the injector.

306 As the electron beam is bent around the racetrack-shaped accelerator of CEBAF and into the  
 307 individual experimental halls, the direction of the horizontal polarization rotates due to spin pre-  
 308 cession. Since the bending angle into the individual halls differ, the launch angle can only be  
 309 optimized for one hall. However, by adjusting the total beam energy and the energy imbalance  
 310 between the North and South linacs, near maximum longitudinal or transverse (horizontal) po-  
 311 larization can be delivered to all halls at certain energies [36, 41].

Figure 6: Spin dance performed in Hall C in February 2019

312 For the proposed measurement, it is desired that the beam is fully polarized in the transverse  
 313 direction. In the case that the Wien filter setting is slightly off the ideal value, there will be a small  
 314 longitudinal polarization of the beam into the hall. We denote this as  $S_L$ . This component can be  
 315 measured using a procedure called spin-dance, see Fig. 6. Comparison of spin-dance with other  
 316 beam diagnostic methods shows that the Wien filter setting can be determined comfortably to a  
 317 level of  $3^\circ$  (5% of the maximum polarization) in precision, though  $1^\circ$  has been reached with careful

318 study [42]. On the other hand, given that  $S_L$  would induce background from PVDIS asymmetry  
319 which is large, we consider a simultaneous fit of  $A_n$  and  $S_L$  from the measured asymmetry in  
320 addition to the method of subtracting the expected  $S_L$  background from the measurement, see  
321 Section 3.2.6.

## 322 2.6 Beam Polarimetry

323 Beam polarization measurements are to be made with the Hall A Moller polarimeter which re-  
324 quires a longitudinally polarized beam. Therefore the horizontal Wien filter at the injector will  
325 have to be adjusted to change the launch angle by  $\pm 90$  degrees prior to each Moller measure-  
326 ment. This process will have to be coordinated with the other halls since it will change the beam  
327 polarization they receive for the length of the Moller measurement (8-16 calendar hours). Given  
328 that other upcoming PVES experiments in Hall A requires 0.4-0.5% precision polarimetry, we ex-  
329 pect to reach the same precision for longitudinally polarized beam. Additional uncertainty could  
330 come from rotation of the Wien filter, though this adds only a negligible  $10^{-3}$  uncertainty to the  
331 polarimetry measurement.

332 In summary, the proposed experiment does not require any new or additional equipment for  
333 the beam polarization measurement, beyond what has already been proposed by the SoLID or  
334 other (MOLLER) collaborations. The Mott polarimeter in the injector can be used without chang-  
335 ing the Wien filter angle, to provide a 2 – 3% precision on the beam polarization, and can be used  
336 in addition to Moller polarimetry.

## 337 3 Rates, Uncertainties and Projected Results

### 338 3.1 Kinematics Settings and Rate Estimation

339 A simulation based on the SoLID detector was used to make reliable estimates about the feasi-  
340 bility and overall impact of the experiment. The simulation is GEANT4 based, using the GEMC  
341 framework to implement each of the detector geometries. The general PVDIS setup was used when  
342 making the estimates. Estimates were made using a 40 cm liquid hydrogen target along with the  
343 full detector setup and the inclusion of baffles. All estimates were made assuming a total of 30 pro-  
344 duction days of running, split between 6.6 and 11 GeV (17 and 13 days), along with an 85% beam  
345 polarization. Figure 7 illustrates the kinematic coverage in  $x$  and  $Q^2$  with the expected rates for  
346 such running conditions. Given the experimental conditions outlined, an estimate of the statistical  
347 uncertainty is shown in Fig. 8.

### 348 3.2 Systematic Uncertainties

349 The proposed experiment will be the first dedicated measurement of the beam-normal single spin  
350 asymmetry in deep inelastic scattering. The total uncertainty of the extracted BNSSAs will largely  
351 be statistics dominated. Many of the systematic uncertainties will enter at a level not expected to  
352 play a dominate role. The main systematic uncertainty for the experiment is from the longitudinal  
353 component of the electron beam polarization during the nominal transverse polarization running.  
354 We will discuss it and briefly discuss several other sources of systematic uncertainties and their  
355 contributions to the measured asymmetry.

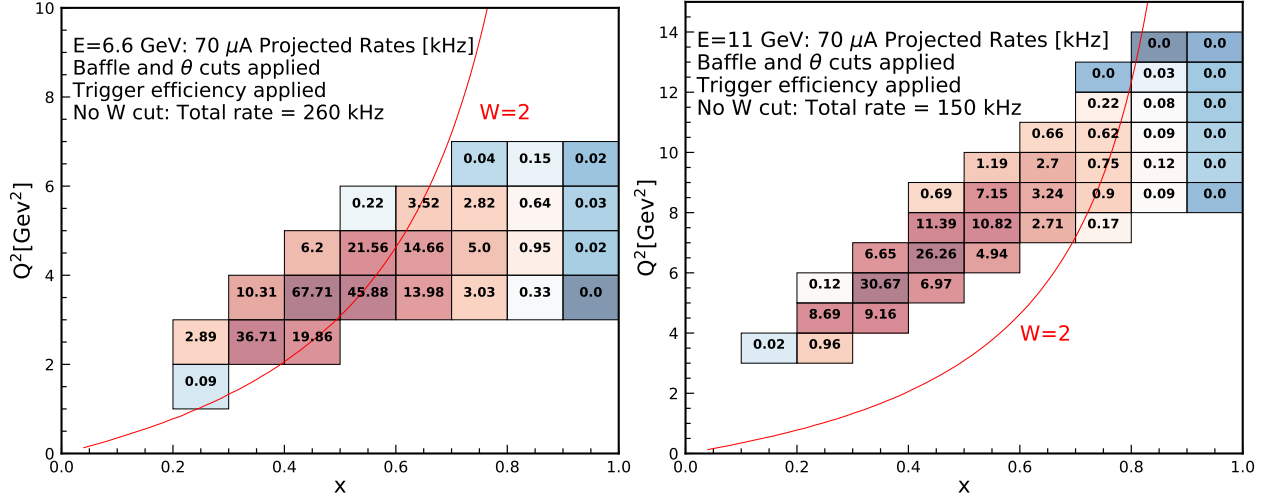

Figure 7: The expected rate in the SoLID PVDIS configuration for the 6.6 GeV (left) and 11 GeV (right) settings. The rates in kHz are shown for each  $(x, Q^2)$  bin. A DIS cut of  $W > 2$  GeV has been applied.

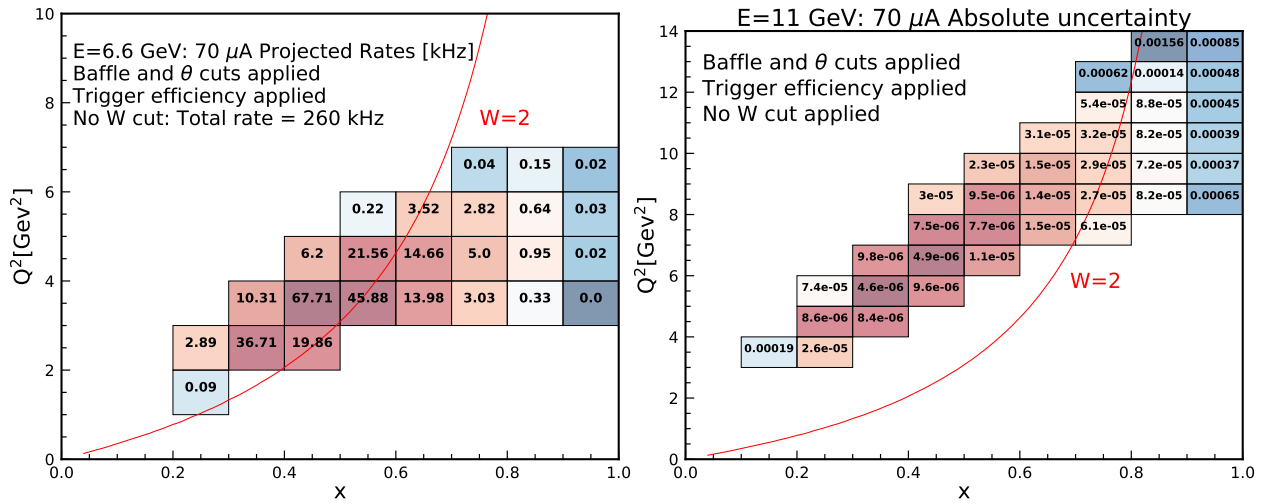

Figure 8: The expected absolute uncertainties in the SoLID PVDIS configuration for the 6.6 GeV (left) and 11 GeV (right) settings.

### 3.2.1 Beam Polarimetry

While upcoming PVES experiments aim to achieve sub-1% on beam polarimetry, we anticipate that a 1% overall uncertainty due to beam polarization to be both (comfortably) achievable and precise enough for the proposed measurement.

### 3.2.2 Target polarization

The ortho hydrogen under 20 K and 1.5 T would be polarized to  $7 \times 10^{-5}$ . The para hydrogen would not have any polarization. As described in Section 2.2, it is relatively straightforward to obtain  $> 99\%$  pure para hydrogen at 20 K. This already limits the possible contribution from target polarization to the measured asymmetry to below 0.5 ppm. The actual physics asymmetry of a

365 transversely polarized beam incident on a longitudinally polarized proton will further reduce this  
 366 effect. We expect the effect from the polarization of the target material to be under 0.1 ppm.

### 367 3.2.3 Target endcaps

368 As described in Section 2.2, the 40-cm long liquid hydrogen target has two aluminum endcaps  
 369 of thickness 120  $\mu\text{m}$  and 150  $\mu\text{m}$  for the entrance (upstream) and exit (downstream) portions,  
 370 respectively. The yield of the  $e-^{27}\text{Al}$  scattering will be determined using an aluminum dummy  
 371 target. On the other hand, the statistics from such dummy target runs will not be sufficient to  
 372 determine  $A_n$  on aluminum to high precision. Since no robust calculation for  $A_n$  is available for  
 373  $^{27}\text{Al}$ , we will not apply a correction to the measured hydrogen asymmetry. Instead, we assume  
 374 that  $A_n$  for  $^{27}\text{Al}$  DIS to be no more than factor 2 different from  $A_n$  for hydrogen, which will result  
 375 in a 5% relative uncertainty.

### 376 3.2.4 $Q^2$ Determination

377 The PVDIS experiment has a requirement of  $\approx 0.2\%$  uncertainty in the determination of  $Q^2$ . This  
 378 has required an intensive study of the experimental design to understand and show how to meet  
 379 this requirement, see [35]. We assume the same can be achieved for the proposed measurement.  
 380 We also note that while it is expected that  $A_n$  may depend on  $Q^2$ , our goal is to determine if  $A_n$   
 381 is significantly larger than the simple parton-model prediction and the 0.2% precision of the  $Q^2$   
 382 more than sufficient in this context. Therefore, we do not anticipate  $Q^2$  determination being a  
 383 major systematic uncertainty.

### 384 3.2.5 Particle Background

385 A major background for DIS experiments comes from charged pions. Detailed estimates for pion  
 386 contamination have been made for the PVDIS experiment, and are applicable for the proposed  
 387 measurement. Utilizing the LGC and the ECal, a pion suppression factor of  $2 \times 10^5$  is expected for  
 388 off-line data analysis and the contamination is estimated to be at 1% level or less for momentum  
 389 above 2 GeV/ $c$ .

390 Another significant background for DIS are electrons from pair production processes. In Fig. 9  
 391 we show an estimate (in percentage) of the anticipated background due to pair production. The es-  
 392 timates were produced using the common Wiser's fit, bench-marked with Hall C 12 GeV data [43].  
 393 We plan to reverse the SoLID magnet polarity to measure the yield of this background and treat  
 394 it as a dilution effect to the measured asymmetry. The uncertainty due to pair production back-  
 395 ground should be below 0.1% for majority of the kinematic bins.

### 396 3.2.6 Beam Longitudinal Spin

397 In the case that the beam carries a longitudinal polarization, it will add a parity-violating (PVDIS)  
 398 asymmetry to the measured data. The PVDIS asymmetry on the proton is independent of  $\phi$  but is  
 399 generally proportional to  $Q^2$ :

$$A_{\text{PVDIS},p} = \frac{3G_F Q^2 [(2U^+ g_{AV}^{eu} - D^+ g_{AV}^{ed}) + Y(2u_V g_{VA}^{eu} - d_V g_{VA}^{ed})]}{2\sqrt{2}\pi\alpha (4U^+ + D^+)}, \quad (5)$$

400 where we have abbreviated PDFs  $q^+ \equiv q(x, Q^2) + \bar{q}(x, Q^2)$  and  $q_V \equiv q(x, Q^2) - \bar{q}(x, Q^2)$  ( $q =$   
 401  $u, d, c, s$ ) and furthermore  $U^+ \equiv u^+ + c^+$  and  $D^+ \equiv d^+ + s^+$ , and have assumed  $c = \bar{c}$  and  $s = \bar{s}$

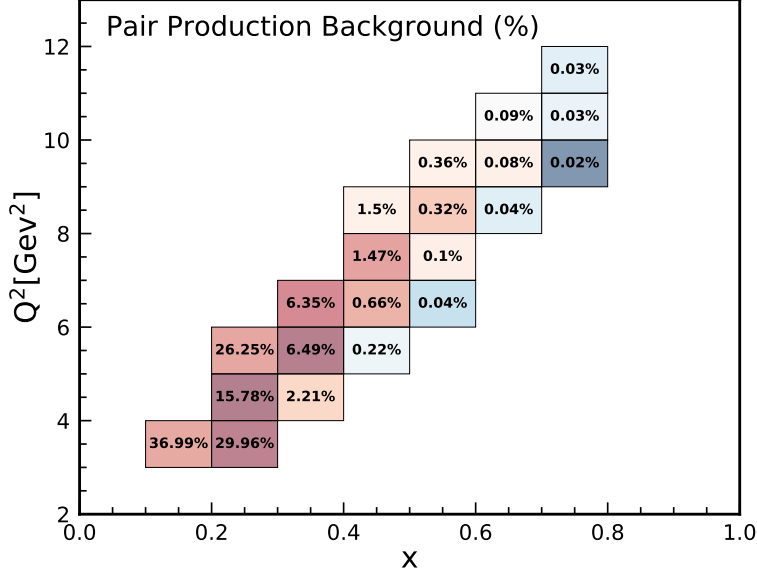

Figure 9: Estimate of the pair produced background using Wiser fit for the 11 GeV setting. A reduced kinematic region was used to make the estimate. The largest background occurs at low  $x$  and high  $y$  values.

402 (and thus  $c_V = s_V = 0$ ). The function  $Y$  is defined as  $Y = [1 - (1 - y)^2]/[1 + (1 - y)^2]$ . The  $g_{AV,VA}^{eq}$   
403 are electron-quark effective neutral-current couplings and are well defined in the Standard Model,  
404 and  $G_F$  is the Fermi constant. One can thus calculate the  $x$  and  $Q^2$  dependence of the PVDIS  
405 asymmetry background using SoLID simulation, and the measured asymmetry will consist of two  
406 contributions: the BNSSA that is  $\phi$ -dependent, and an additional term  $S_L A_{\text{PVDIS},p}(x, Q^2)$  that is  
407 independent of  $\phi$  where  $S_L$  is the beam longitudinal spin component. The value of  $S_L$  can also be  
408 measured through a spin-dance procedure and determined to a 3° level, as described in Section 2.5.  
409 However, due to the large size of PVDIS asymmetry, at about 70-80 ppm multiplied by  $Q^2$  values  
410 (in GeV<sup>2</sup>), we found it is advantageous to treat  $S_L$  as a fitting parameter rather than using spin-  
411 dance result, see Section 3.3.

### 412 3.2.7 Beam In-Plane Transverse Polarization

413 If the spin of the incoming electron is polarized transversely but in the scattering plane, there can  
414 be a parity violation asymmetry for scattering off an unpolarized target. It would be similar to the  
415 asymmetry of an unpolarized electron scattering off a polarized proton with opposite spin direc-  
416 tion, except that one swaps out the proton polarized structure functions  $g_{1,2,3,4,5}^{\gamma Z}$  by the counterparts  
417 of a Dirac fermion (the electron). Experimentally, such asymmetry will show up as a  $\cos(\phi)$  con-  
418 tribution. We expect this asymmetry to be that of typical PVES and further suppressed by  $m_e^2/Q^2$   
419 because of the transverse spin, and is much below the ppm level. In any case, it can be calculated  
420 precisely using a complete leptonic tensor that accounts for transverse spin of the electron, and the  
421 typical DIS hadronic tensor that can be readily expressed in terms of PDFs.

### 422 3.2.8 Summary of Systematic Uncertainties

423 We show in Table 3 a summary of all systematic uncertainties. As described in the next section,  
424 we expect that statistical uncertainty on the extracted  $A_n$  to be at 10% (2 ppm) level or larger and

425 dominate the uncertainty of the proposed measurement. At the mean time, the effect of beam  
 426 longitudinal polarization and spin angle are dealt with in the data analysis step and are not shown  
 427 in the table.

Target endcaps	5%
Polarimetry	1.0%
Particle background	1.0%
$Q^2$ determination	0.2%
Target polarization	under 0.1 ppm
Total systematic	5.2%

Table 3: Systematic uncertainty for the proposed measurement, shown as relative uncertainty in the measured asymmetry unless specified otherwise.

### 428 3.3 Data Analysis and Projected Results

429 The raw BNSSA asymmetry will be determined according to:

$$A_{\text{raw}} = \frac{1}{P_b} \frac{N^\uparrow(\phi) - N^\downarrow(\phi)}{N^\uparrow(\phi) + N^\downarrow(\phi)}; \quad (6)$$

430 where  $P_b$  is the beam polarization, and  $N^\uparrow$  and  $N^\downarrow$  are charge normalized yields for electrons polarized perpendicular – left and right or up and down – to the electron’s momentum, respectively.  
 431  
 432 The BNSSA,  $A_n$ , can subsequently be extracted from the raw asymmetry distributions.

433 As mentioned in the previous section, a longitudinal component of the beam polarization ( $S_L$ )  
 434 will result in a residual PVDIS asymmetry. This can introduce a sizable uncertainty in the measured asymmetry and the subsequently extracted BNNSA. To understand the effect the  $S_L$  will  
 435 have on our projected BNSSA, we performed a multi-parameter fitting study as follows:  
 436

- 437 1. Perform a simulation using the GEMC SoLID Monte Carlo generator to determine the statistical precision that can be achieved in each  $(x, Q^2)$  bin given the luminosity, acceptance profile, and DAQ rate limit of the PVDIS configuration. The beam polarization  $P_b$  is corrected in this step, i.e.  $\Delta A_{\text{stat}}^i = 1/\sqrt{N_i}/P_b$  with  $N_i$  the event count expected for the  $i^{\text{th}}$  bin.
- 438 439 440 2. Generate pseudo-data on the asymmetry following a  $A_n \sin(\phi)$  form in each  $Q^2$  bin, with a random number  $r_i$  generated in each  $Q^2$  bin to mimic the effect of the statistical fluctuation based on the uncertainty calculated from the previous step. The value of  $A_n$  is assumed to be a constant 20 ppm.
- 441 442 443 444 3. Generate a random number  $r_s$  within 5% of the maximum polarization, to account for the longitudinal component  $S_L$  of the beam polarization. This random number applies to all  $Q^2$  bins of the same beam energy. The pseudo data in each  $Q^2$  bin now read:

$$A_{\text{raw,pseudo-data}}^{i^{\text{th bin}}} = 20 \text{ ppm} \sin(\phi) + r_i \Delta A_{\text{stat}}^i + r_s A_{p,\text{PVDIS}}^i$$

445 where  $A_{p,\text{PVDIS}}^i$  is the proton PVDIS asymmetry calculated for the  $i^{\text{th}}$  bin.

- 446 4. From here, there are 3 possible analysis methods to extract  $A_n$ :

- 447 • Subtract  $S_L A_{\text{PVDIS}}$  from the pseudo data and then fit the  $\sin \phi$  form. In this case, the  
448 value of  $S_L$  is the same as  $r_s$  but the  $3^\circ$  (5%) uncertainty in  $S_L$  needs to be accounted  
449 for in the asymmetry after the subtraction.
- 450 • Perform a multi-parameter fit of the form  $A_n \sin(\phi) + B A_{\text{PVDIS}}$ , where  $D$  is a parameter  
451 that corresponds the longitudinal component,  $S_L$ .
- 452 • Perform a  $\sin \phi$  weighted integral in  $\phi$  to extract  $A_n$ . The  $S_L$  component vanishes with  
453 the integration.

454 We studied all three methods described above in order to best minimize the total uncertainty  
455 on the extracted  $A_n$ . We found that the multi-parameter fit produces the best result. The multi-  
456 parameter fit takes the general form, for each bin:

$$\begin{aligned}
 f_1 &= C_1 \cdot \sin(\phi + \phi_{\text{off}}) + D \cdot A_{p,\text{PVDIS}} \\
 f_2 &= C_2 \cdot \sin(\phi + \phi_{\text{off}}) + D \cdot A_{p,\text{PVDIS}} \\
 &\vdots \\
 f_N &= C_N \cdot \sin(\phi + \phi_{\text{off}}) + D \cdot A_{p,\text{PVDIS}},
 \end{aligned} \tag{7}$$

457 where  $f_i$  is the fitting function for the pseudo data in the  $i^{\text{th}}$  bin, the  $C_i$  coefficients correspond to  
458 the fitted BNSSA in each  $Q^2$  bin,  $\phi_{\text{off}}$  is a phase factor that accounts for possible mis-alignment of  
459 the detector, and  $D$  is a parameter that corresponds to the longitudinal component of the beam  
460 polarization  $S_L$ . We found the fitted uncertainty on  $S_L$  to be at 1% level or below, better than the  
461  $3^\circ$  (even the  $1^\circ$ ) uncertainty of the Wien angle determination.

### 462 3.4 Projected DIS Results

463 Applying the methods outlined above, we were able to make reasonable estimates of the BNSSA  
464 extraction and its uncertainties. In Figs. 10 and 11, we show the  $\phi$  dependence of  $A_n$  across different  
465  $Q^2$  for 6.6 and 11 GeV, respectively. Both statistical and systematic uncertainties are included along  
466 with a DIS cut of  $W > 2$  GeV.

467 By performing the multi-parameter fit of Eq. (7), we extracted the individual BNSSA values  
468 for each  $Q^2$  bin of size  $1 \text{ GeV}^2$ . These are shown in Fig. 12 and 13 for the 6.6 and 11 GeV settings,  
469 respectively. Additionally, the individual BNSSA values from different  $Q^2$  bins were combined,  
470 which provided an uncertainty of 2.1 and 3.8 ppm. A summary plot of the extracted BNSSA values  
471 is given in Fig. 14 and compared with the existing 6 GeV PVDIS data. The systematic uncertainty  
472 (not shown) is expected to be  $\approx 5\%$  and is much smaller than the statistical uncertainties.

473 Finally, we note that inelastic events in the nucleon resonance region will be accepted by SoLID  
474 detectors and we can in principle extract  $A_n$  in the nucleon resonance region. However, our knowl-  
475 edge on the resonance  $A_{\text{PV}}$  is limited, and one cannot perform a precise determination of resonance  
476  $A_n$  without studying carefully the precision on  $A_{\text{PV}}$  as well. Therefore, we will present the fitted  
477 results on the resonance  $A_n$  in Appendix A, accounting only the statistical uncertainty.

### $A_n(\phi)$ Distribution: 6.6 GeV

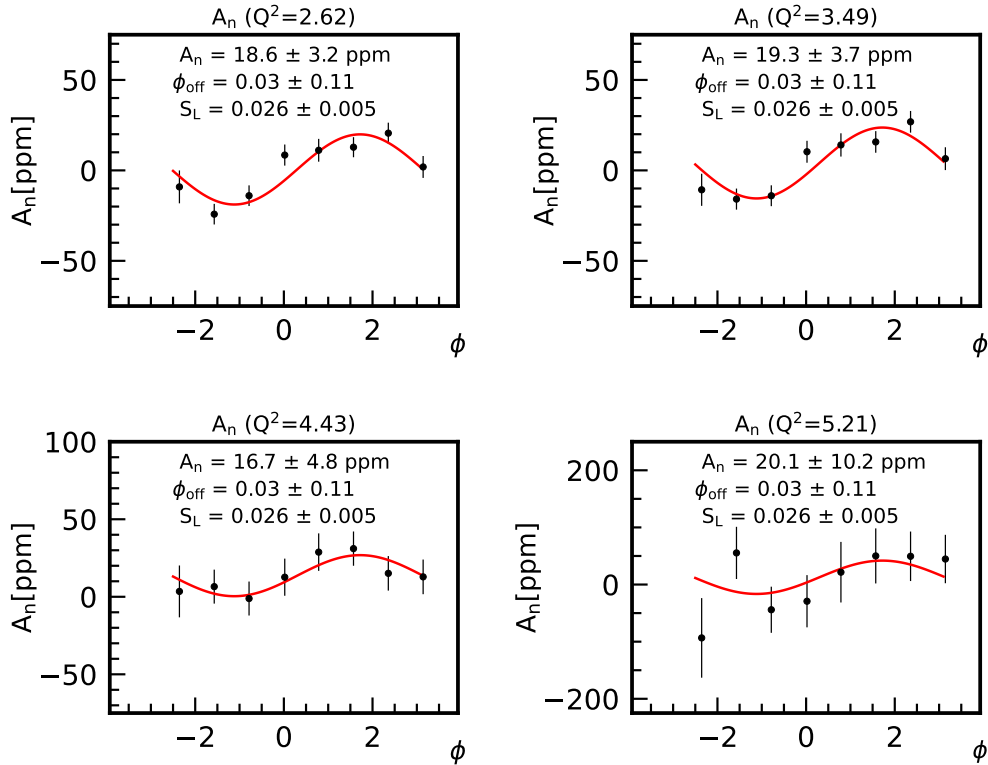

Figure 10: Generated pseudo data for the 6.6 GeV beam energy setting with a  $W > 2$  GeV cut to select DIS events. A common value of the 20 ppm was assumed for the size of  $A_n$ . An input value of 0.0150 was used as an input for  $S_L$ . The uncertainty in the fitted  $S_L$  coefficient was found to be at a level of 0.52%.

### $A_n(\phi)$ Distribution: 11 GeV

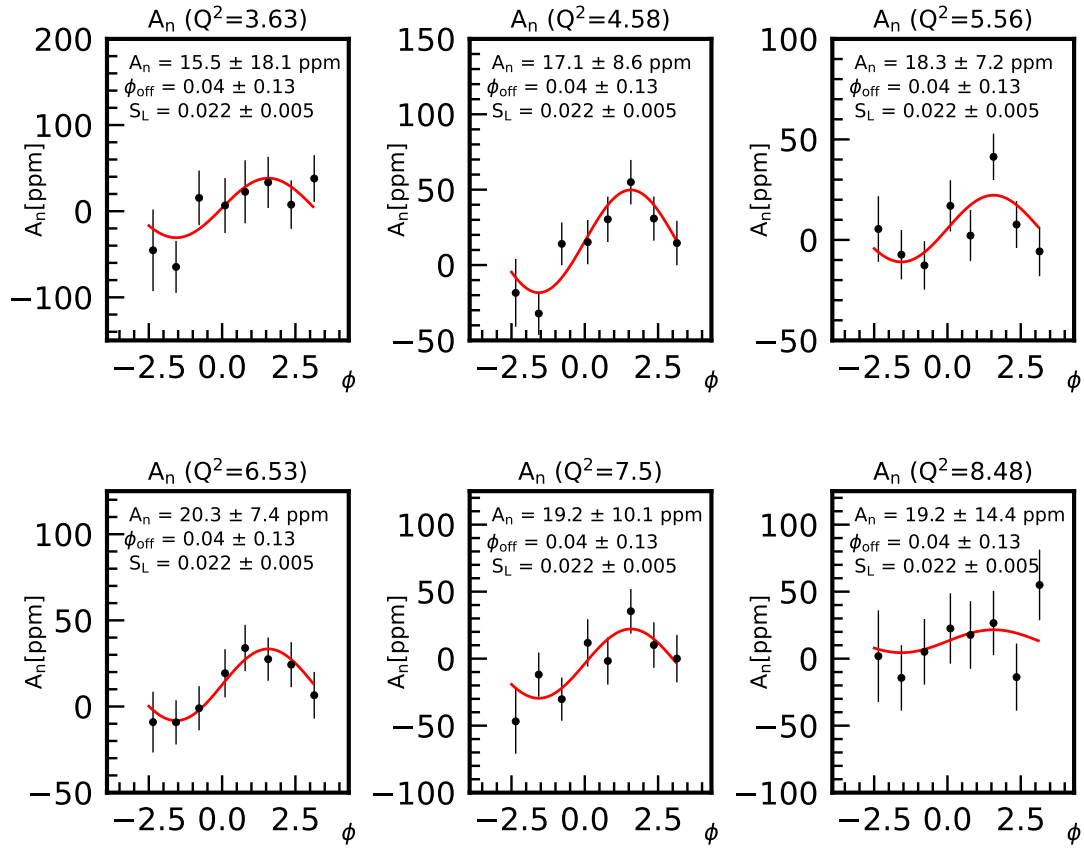

Figure 11: Same as Fig. 10 but for the 11 GeV beam energy setting. The uncertainty in the fitted  $S_L$  coefficient was found to be at a level of 0.47%.

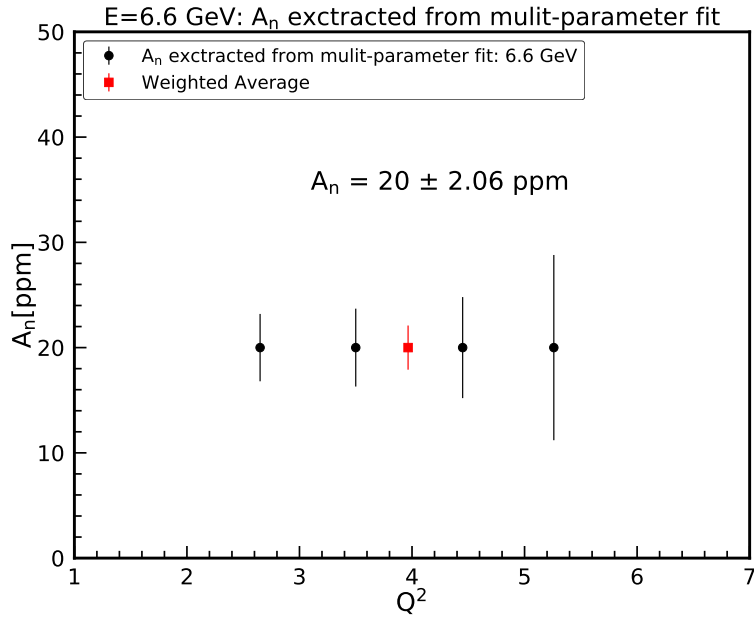

Figure 12: Projected results on DIS BNSSAs extracted with a multi-parameter fit for the 6.6 GeV data. The black dots represent the fitted BNSSA in each  $Q^2$  bin while the red square at the center is the weighted average combined over all  $Q^2$  values. The projections were made assuming 17 PAC days of running at  $70\mu\text{A}$ .

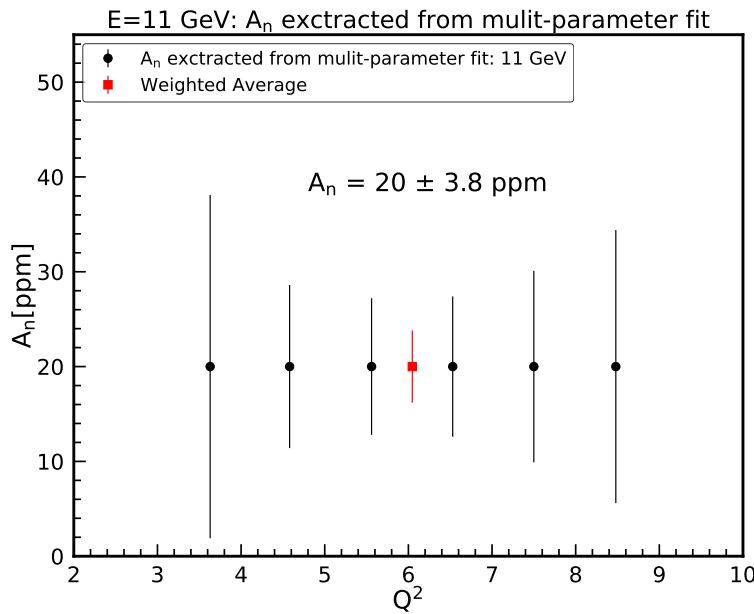

Figure 13: Projected results on DIS BNSSAs extracted with a multi-parameter fit for the 11 GeV data. The black dots represent the fitted BNSSA in each  $Q^2$  bin while the red square at the center is the weighted average combined over all  $Q^2$  values. The projections were made assuming 13 PAC days of running at  $70\mu\text{A}$ .

Figure 14: The projected uncertainties on  $A_n$  vs.  $Q^2$  from the 6.6 GeV (red) and 11 GeV (blue) beam energy settings of the proposed experiment. A cut of  $W > 2$  GeV was applied to select only DIS events. The 6 GeV PVDIS BNSSA data (black) [16] are also shown for comparison.

#### 478 **4 Beam Time Request**

479 We request a total of 38 PAC days of beam time, among which 30 days will be for production  
 480 running on a 40-cm liquid hydrogen target with a transversely polarized beam of 85% polarization.  
 481 Among the 38 days, 17 days will be spent at 6.6 GeV and 13 days at 11 GeV. In order to determine  
 482 the beam polarization, we will require 4 days of dedicated polarimetry measurements, taking into  
 483 account the additional time needed to rotate the Wien filter angle. The remaining 4 days will be  
 484 used for commissioning and calibration, including reverse solenoid polarity runs to determine the  
 485 pair production background. Table 4 summarizes our beam time request.

Purpose	Time (Days)	Energy (GeV)	Beam Current ( $\mu\text{A}$ )
Commissioning	2	varies	as needed
Polarimetry	4	varies	as needed
Pass change	0.67	N/A	as N/A
Reverse SoLID polarity	0.67	N/A	N/A
Reverse polarity run	0.33	6.6	70
Reverse polarity run	0.33	11	70
40-cm LH <sub>2</sub> Production	17	6.6	70
40-cm LH <sub>2</sub> Production	13	11	70

Table 4: Beam time request for the proposed experiment.

## 486 5 Summary

487 We propose a high precision measurement of the beam-normal single-spin asymmetry (BNSSA)  
488  $A_n$  of the proton in the deep inelastic scattering region. We request a total of 38 PAC days of trans-  
489 versely polarized beam, among which 17 days will be for production at 6.6 GeV and 13 days at 11  
490 GeV, both with a current of  $70\mu\text{A}$ . Additional 4 days are requested for beam polarimetry measure-  
491 ment and 11 days for commissioning, pass change, and calibration, including reverse polarity runs  
492 to determine the pair production background. The projected uncertainty on the extracted  $A_n$  in the  
493 DIS region, if combining all  $Q^2$  bins, is about 2.1 ppm for the 6.6 GeV and 3.8 ppm for the 11 GeV  
494 setting. The  $Q^2$  dependence of  $A_n$  will be studied by dividing data into  $Q^2$  bins. This will be the  
495 first dedicated measurement of BNSSA in DIS to ppm precision. It will test two-photon-exchange  
496 (TPE) calculations for BNSSA in DIS. If there exists any effect that amplifies BNSSA predicted by  
497 the simple parton-model of TPE, it will be revealed by the proposed measurement.

498 **A Projected Results: Resonance**

499 While not the main focus of this proposal, the SoLID detector would accept a wide range of nucleon  
 500 resonance scattering event. We investigated the uncertainty of the BNSSA in the resonance region  
 501 following the same procedure as in the DIS case but now with a  $W < 2$  cut. We show in Fig. 15  
 502 the  $\phi$  distribution of generated pseudo data at 6.6 GeV and the projected results on  $A_n$  in Fig. 16  
 503 obtained from the multi-parameter fit. The uncertainty of the resonance  $A_n$  extraction from the 11  
 504 GeV setting is larger and the details are omitted here.

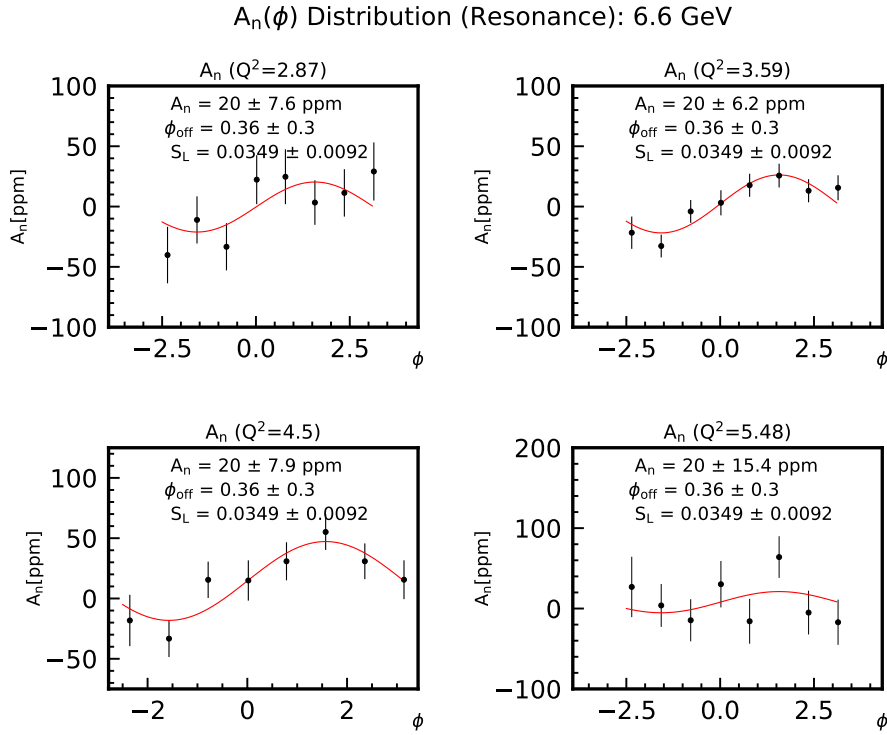

Figure 15: Generated pseudo data for the 6.6 GeV beam energy setting with a  $W < 2$  GeV cut to select DIS rates. A common value of the 20 ppm was assumed for the for the size of  $A_n$ . The uncertainty in the fitted  $S_L$  coefficient was found to be at a level of 0.9%.

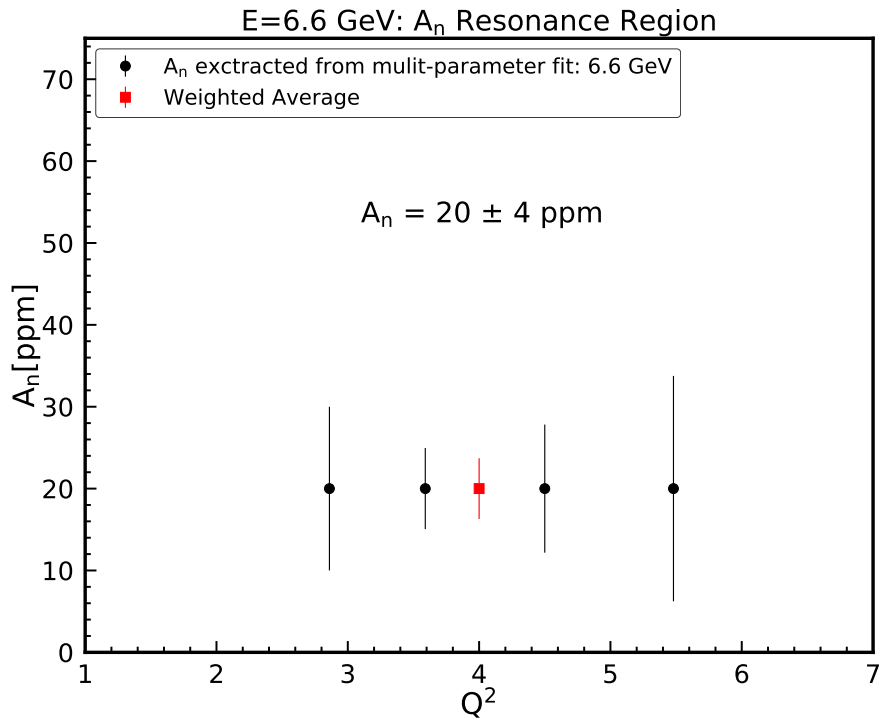

Figure 16: Projected BNSSA along with the weighted average value in the resonance region for 6.6 GeV setting.
