ABSTRACT

We propose to measure the branching ratios of the electromagnetic decays of the low lying excited hyperons, using the CEBAF LAS. An excited hyperon will be produced using a tagged photon beam with $\Delta E_\gamma/E_\gamma = 0.25\% \ FWHM$, via the reaction $\gamma p \rightarrow K^+ Y^-$. The kaon, decay $\gamma$ and the proton and $\pi^-$ from the final state $\Lambda$ will be detected. The four momentum of the hyperon will be reconstructed from the beam photon energy and the kaon momentum. The four momentum of the $\Lambda$ will be reconstructed from the proton and $\pi^-$ momenta. FASTMC modeling of the system indicates that the hyperon mass will be determined to better than 5 Mev FWHM and the $\Lambda$ mass to better than 2 Mev FWHM. With such good mass resolution the backgrounds due to $\pi^0$ decays can be efficiently suppressed for the $Y^- \rightarrow \gamma \Lambda$ decays. However, a large coverage, fine grained shower counter is required to reduce the $\pi^0$ background for $Y^- \rightarrow \gamma \Sigma^0$ decays.
I. Introduction

We propose to measure the electromagnetic branching ratios of the low lying states of the $\Lambda$ and $\Sigma$ hyperons. The accessible states and allowed electromagnetic decay modes are shown in Figure 1. Recent experimental activity\textsuperscript{1-4} in this field has stimulated theoretical interest\textsuperscript{5-10} in the electromagnetic decays. Much of this work is summarized in a paper by Goldman et al.\textsuperscript{1} which is included as an Appendix. To summarize the points made in this paper, the ground states of the $\Lambda$ and $\Sigma^0$ hyperons, in a simple three quark model, have ground states composed of an up, down and strange quark, all in an $S_{\frac{1}{2}}$ orbit. The light quarks are coupled to total spin and isospin $S = 0$ and $T = 0$ for the $\Lambda$ and to $S = 1$ and $T = 1$ for the $\Sigma^0$ as shown in Figure 1. The strange quark is then coupled to give a $J = \frac{1}{2}^+$ ground state, with $T = 0$ for the $\Lambda$ and $T = 1$ for the $\Sigma^0$. The excited states are formed by exciting one quark to a different spin or orbital state. Photoemission occurs by the deexcitation of this quark. The first $T = 1$ excited state is the $\Sigma^-(1385)$ with $J = \frac{3}{2}^+$. This is formed by a spin flip of the strange quark. This state can decay to either the $T = 0$ or the $T = 1$ ground state by an $M1$ transition. The first excited $T = 0$ state, the $\Lambda^-(1405)$, has a strange quark excited to the $P_{\frac{3}{2}}$ orbital, yielding a $J = \frac{1}{2}^-$ state. This can decay to the $T = 0$ ground state by an $E1$ transition. However, in the naive model we are considering here, the transition to either $T = 1$ state is strictly forbidden, as it would require a two quark interaction. The second excited state, the $\Lambda^*(1520)$, is predicted to be a linear combination of states with either a strange quark or one of the light quarks in the $P_{\frac{3}{2}}$ orbital, all coupled to a $J = \frac{3}{2}^-$ state. As before the $\Lambda^*(1520)$ is forbidden to decay to the $\Sigma^-(1385)$, due to the one-body nature of the electromagnetic operator.

The structure of these states is not well understood. The nature of the $\Lambda(1405)$ has been in dispute for many years. Originally it was interpreted as an antikaon-nucleon bound state\textsuperscript{11}. With the advent of nonrelativistic quark models (NRQM) it was interpreted as a more or less normal three quark state\textsuperscript{12} although it stands out in quark models as one state whose energy is particularly hard to fit. For example, the Isgur-Karl NRQM calculation predicts the center of gravity of the $\Lambda(1520)$ and $\Lambda(1405)$, but does not correctly predict the mass splitting. More recently cloudy bag
model (CBM) calculations by Valt et al. find that the \( \Lambda(1405) \) is predominately an antikaon-nucleon bound state with some small admixture of three quark states. It is very difficult to decide which interpretation is correct from strong interaction data alone, since the \( \Lambda(1405) \), which is below the \( \bar{K}N \) threshold, is seen only in \( \Sigma\pi \) production and through its effect on the low-energy \( \bar{K}N \) S-wave.

The best test of the internal structure of these hyperon states is a measurement of their electromagnetic transitions since these experiments should be significantly easier to interpret. The radiative widths have been calculated by a number of groups, and their results are listed in Table I. Darewych et al. used the Isgur-Karl quark model. Moniz, Soyeur and Kaxiras used a fixed radius static cavity approximation to the MIT bag model. Finally Kaxiras used the Isgur-Karl model with two different sets of basis states, labelled \( SU(6) \) and uds. The values quoted for the last three calculations are taken from ref. 1. As can be seen from Table I the theoretical values can vary by as much as a factor of 60, with the forbidden transitions allowed in some models. Furthermore, other models are possible, such as an admixture of \( q\bar{q} \) states, that lead to larger rates. See ref. 1 for further details. Thus the measurement of electromagnetic transition rates provide a very sensitive test of the various quark models. For example, DHK point out that a large radiative width for the \( \Lambda^*(1520) \) and \( \Lambda^*(1405) \) to the \( \Sigma \)'s would imply that color hyperfine forces are present in these systems.

II. Existing Measurements

There are only a limited number of measurements of neutral hyperon electromagnetic decays. The radiative width of the \( \Sigma^0(1193) \) to \( \gamma\Lambda(1116) \) decay has been measured by Dydak et al. to be \( 11.5 \pm 2.6 \) keV. There are two measurements of the radiative width of the \( \Lambda(1520) \) to \( \gamma\Lambda(1116) \) decay, using the reaction \( K^- p \rightarrow \gamma\Lambda \). Mast et al., using a bubble chamber, found 258 events, 15\% of which were assumed to be \( \gamma\Sigma^0 \) events. The amount of this background depends on the unmeasured \( \Lambda(1520) \rightarrow \gamma\Sigma^0 \) branching ratio. They obtained a radiative width of \( 150 \pm 30 \) keV. Their measured angular distribution was consistent with an E1 transition. A recent, unpublished, CERN experiment, using a large NaI detector, found a radiative width in serious disagreement with Mast.
et al. Finally there exists a weak upper limit on the radiative decay of the $\Sigma^0(1385)$ from Colas et al.\textsuperscript{18} They find an upper limit of about 2000 keV, which does not constrain any of the models.

The branching ratio for radiative capture $K^- p \rightarrow \gamma \Lambda$ has been measured by Humphreys and Ross,\textsuperscript{19} Davies et al.,\textsuperscript{20} Lowe et al.\textsuperscript{4} and Whitehouse et al.\textsuperscript{2} Whitehouse et al. also have measured the $K^- p \rightarrow \gamma \Sigma^0$ branching ratio. The results for these experiments are given in Table II, along with the current theoretical predictions. The most precise results are due to Whitehouse et al., who measured the photon spectrum from $K^-$ stopping in a liquid hydrogen target with a high-resolution (1.5% $FWHM$ at 300 $MeV$) $NaI(Tl)$ detector. Their data are shown in Figure 2. They have a total of 499 $\gamma \Lambda$ events and 850 $\gamma \Sigma^0$ above a substantial $\gamma$ continuum. Their results are a factor of two below the theoretical predictions. There is considerable controversy among theorists concerning the degree to which the $K^- p$ radiative capture creates the $\Lambda(1405)$ as an intermediate state, which leads to theoretical uncertainties in extracting the radiative width from these data.\textsuperscript{7,8,9,10}

In the experiment proposed here, these difficulties will not exist. A clean, tagged sample of $Y^+$ will be created through the reaction $\gamma p \rightarrow K^+ Y^+$. The radiative decay of the excited hyperon can then be observed free of strong interaction effects in the formation channel. Unfortunately, photoproduction does not distinguish between the $I = 0 \ \Lambda(1405)$ and the $I = 1 \ \Sigma^0(1385)$. This will present difficulties. Nevertheless, comparison of our results with the results of the $K^- p \rightarrow \gamma \Lambda, \gamma \Sigma^0$ experiments will give the theorists valuable new data against which to test their various models.

III. Technical Details of Proposed Experiment

A. Introduction

A beam of tagged hyperons can be produced by detecting the kaon from the reaction

$$\gamma p \rightarrow K^+ \Lambda^-(\Sigma^-)$$

using the proposed LAS.\textsuperscript{21} A tagged photon beam will be used to reduce the background due to Möller scattering of electrons and to establish the kinematics of the initial state.
The radiative decay of the excited hyperon is then signaled by the decay sequence.

\[ \gamma p \rightarrow K^+ Y^- \rightarrow K^+ \gamma \Lambda \rightarrow K^+ \gamma \pi^- \]  \hspace{1cm} (2)

A typical event is shown in Figure 3. The four momentum of the \( \Lambda \) is reconstructed from the measured \( \pi^- p \) momenta, while the four momentum of the excited hyperon is reconstructed from the beam photon energy and the kaon momentum. From this information the decay photon four momentum can be calculated. Substantial background suppression can be obtained by verifying that a photon was detected in the shower counter at the appropriate element of phase space.

The \( \Lambda^+ \) radiative decays proceeding via the \( \Sigma^0 \) have a more complicated signature:

\[ \gamma p \rightarrow K^+ Y^- \rightarrow K^+ \gamma \Sigma^0 \rightarrow K^+ \gamma \Lambda \rightarrow K^+ \gamma \pi^- \]  \hspace{1cm} (3)

This requires the reconstruction of the \( Y^- \) and \( \Lambda \) four momentum as before, but now the detection of the \( \Sigma^0 \) decay photon is necessary to determine the three momentum of the \( \Sigma^0 \). (The four momentum could of course be determined if the photon energy were well determined. But this will not be the case for the \( 70\text{MeV} \) photon. Thus we assume the \( \Sigma^0 \) mass and calculate the three momentum.) Again detection of the \( Y^- \) decay photon greatly suppresses the background. In this case however, it is really a part of the zero constraint fit, because each low energy photon contributes only two angles, due to the poor energy resolution of the shower counter. This will be discussed in more detail in the section on modeling. The most serious background is the emission of a \( \pi^0 \) instead of a photon in the \( Y^- \) decay. With radiative branching ratios of \( 10^{-2} \) to \( 10^{-3} \), good \( \pi^0 \) suppression is essential.

B. FASTMC Simulation of the Experiment

The experiment has been simulated using the program, FASTMC.\textsuperscript{22} The assumed system parameters are given in Table III. All parameters not listed are as given in the CDR. Schumacher\textsuperscript{23} has shown that the acceptance of the LAS for \( \gamma p \rightarrow K \Lambda \) is maximized by bending positive particles toward the beamline and reducing the magnetic field to 20% of full strength, (due to low momentum of the \( \pi^- \)). Therefore we have made the appropriate changes in FASTMC and adopted this set of conditions to insure
the \( \pi^0 \) gammas misidentified as the \( \Sigma^0 \) decay gamma. Imposing a second \( \gamma \) coincidence requirement greatly reduces this background, but also reduces the \( \gamma \Sigma^0 \) peak, as is shown in Figure 6b. The mass resolution is adequate, but the rate is quite low due to the limited shower counter coverage.

Figures 7, 8, and 9 show the FASTMC results for the reactions

\[
\gamma p \rightarrow K^+ \gamma^* \quad (8)
\]

where \( \gamma^* \) is either the \( \Sigma^0(1385) \) or the \( \Lambda(1405) \). Here a tagged photon beam of 0.7 \( E_e \) to 0.9 \( E_e \) with \( E_e = 2.4 \text{ GeV} \) was used. Again the figures represent 100 hour’s running. Since the \( \gamma \Lambda \) and \( \gamma \Sigma^0 \) branching ratios are an order of magnitude smaller than in the \( \Lambda(1520) \) decays, and the \( \pi^0 \) branching ratios are four times larger (See Table IV), the \( \pi^0 \) related backgrounds are much larger relative to the \( \gamma \Lambda \) and \( \gamma \Sigma^0 \) signals. The \( \gamma \Lambda \) decays are still well separated from the \( \pi^0 \) continuum, as shown in Figure 8. However the \( \gamma \Sigma^0 \) signal is overwhelmed by the \( \pi^0 \) background as shown in Figure 9a. In Figure 9b we can see a clear \( \gamma \Sigma^0 \) signal above about a 20% background. But increased shower counter coverage is needed to improve the count rate.

Figure 10 shows the \( \Lambda(1405) \) and \( \Sigma^0(1385) \) mass spectrum for events that satisfies the \( \gamma \) mass cut in Figures 5a and 8a. The figure represents 500 hours of data. Clearly it will be difficult to separate the \( \Sigma^0(1385) \rightarrow \gamma \Lambda \) decays from the \( \Lambda(1405) \) decays due to their large widths and low count rates.

**C. Count Rates and Background Estimations**

We assume a tagged photon beam with an intensity of \( 10^7 \gamma/\text{sec} \) and an energy range of 0.7 – 0.9\( E_e \) for \( E_e = 2.4 \text{ GeV}, \) (\( E_e = 1.7 – 2.2 \text{ GeV} \)), and 0.6 – 0.8 \( E_e \) for \( E_e = 3.2 \text{ GeV}, \) (\( E_e = 1.9 – 2.6 \text{ GeV} \)). The total photoproduction cross section for \( \Lambda \)'s and \( \Sigma^0 \)'s is about 1\( \mu b \) in the energy range \( E_e \) between 1 and 2 GeV. The total cross section for \( \Lambda(1520) \) photoproduction cross section is also about 1\( \mu b \) at 2.25 GeV.\(^{25,26}\) The \( \Lambda(1405) \) and \( \Sigma^0(1385) \) total cross sections were taken to be comparable, lacking any other information. Therefore, using a liquid hydrogen target of 1.0g/cm\(^2\), the \( \gamma p \rightarrow K^+ \gamma \) reaction rate is estimated to be about 6 events/sec for each hyperon. These rates must be reduced by the \( \Lambda \rightarrow p\pi^- \) branching ratio, (0.64), the branching
ratios leading to Λ’s in the final state (See Table IV), the decay probabilities of the kaon and π⁻, and the LAS acceptance.

From the FASTMC simulations, we find that the acceptance is about 8% for $K^+ - p - π^-$ events and 3% for $K^+ - p - π^- - γ$ events. The decays of the kaon and π⁻ further reduce the rate by a factor of four. Table Va gives the count rate per 100 hours for the various reactions.

These low data rates could be increased by the following methods:

1). Move the target upstream by 50 - 100 cm. This will increase the acceptance for the forward going $K^+$. However it will reduce the shower counter solid angle, and reduce the $γΣ^0$ count rate.

2). Increase the beam intensity to $2 \times 10^7$ or even $3 \times 10^7$. This will increase the tagger deadtime 2 - 3 fold, and the accidental triggers due to the reaction $γp → π^+ + pπ^- 4 - 9$ fold. This may generate too many accidental events which could overload the Level 4 trigger and lead to too many events being written to tape. A possible solution to this problem might be to install a scintillating fiber vertex detector around the liquid hydrogen counter. A vertex detector with nanosecond response time would eliminate the accidentals from adjacent machine bunches and greatly reduce the trigger rate. The Rice University group will explore the design of such a detector.

3). Add a small, good energy resolution photon detector in the back angles ($60° - 160°$, for example). Such a detector would be used to detect the 70 $Mev$ $Σ^0$ decay photon. There is a proposal at BNL to study the feasibility of using pure $CsI$ crystals as a high rate electromagnetic calorimeter. $CsI$ has fast uv emission with decay constants of 10 and 35 ns. The light output, with a suitable waveshifter, is 20% that of $NaI(Tl)$ and twice that of BGO. This, in conjunction with moving the target upstream, may be the best way to look for the $γΣ^0$ decays. Further feasibility studies are required to evaluate this option.

D. Trigger and Particle Identification

The trigger must select events with a $K^+$ in coincidence with the Λ decaying into $pπ^-$. As we have seen from the simulation, we do not want to put the $γ$ in the trigger if we can avoid it. It is a powerful tool to reduce background, but it also reduces the
count rate. The total hadronic production rate in the target is estimated to be only of the order of $2 \times 10^4$ particles/sec so that the $\gamma$ coincidence is not needed to reduce the trigger rate. Thus the first stage of the trigger would be:

**Level 1 and 2 Trigger**

a). signal from the Tagger,
b). two (positive) charged particles hitting the LAS T-O-F scintillator
c). one (negative) charged particle in the LAS drift chambers.

This trigger will also select the reaction

$$\gamma p \rightarrow \pi^+ p\pi^-$$  \hspace{1cm} (9)

Thus the trigger must discriminate against such events. From FASTMC simulation studies we find that the $K^+$ and proton are limited to less than $60^0$ and the $\pi^-$ is less than $0.4$ GeV/c. See Figures 11 and 12. Thus higher level trigger cuts to impose would be

**Level 3 Trigger**

d). $\theta \leq 60^0$ for the positive charged particles
e). $P < 0.5$ GeV for the negative charged particle.

Finally to select a $K^+$,

**Level 4 Trigger**

f). The T-O-F vs. $P$ of one of the positive charged particles should be consistent with a kaon.

Since the kaon momentum of interest is less than $1.5$ GeV/c, this will be an effective off-line cut, (except for accidentals), but how effective an on-line cut it will be will depend on the on trigger momentum resolution. Figure 13 shows the T-O-F versus momentum plot for kaons and $\pi^+$ from the reactions

$$\gamma p \rightarrow K^+ Y^-$$  \hspace{1cm} (10)

and

$$\gamma p \rightarrow \pi^+ p\pi^-$$  \hspace{1cm} (11)
There is a clear separation for these reactions, which will give good \( \pi^+ \)-kaon separation. Note that it might be possible to add a T-O-F greater than 15 ns. cut to the Level 1 trigger. Figure 14 shows the background \( \pi^+p\pi^- \) data, but with the beam photon shifted by two nanoseconds. Clearly some accidentals will satisfy the trigger.

The estimated trigger rates/sec are given in Table VI, for the conditions listed in the count rate section. The \( \gamma p \rightarrow K^+\Lambda \) trigger rates have the various branching ratios folded in. The reaction \( \gamma p \rightarrow \pi^+p\pi^- \) has an average cross section of about 45 \( \mu b \) in the energy range of tagged photons, (1.7 - 2.2 GeV). The trigger rate for these events are also given in the table. Finally the trigger rates for this reaction from untagged photons is given. In this calculation it was assumed that the accidental rate for a untagged photon to give a \( \pi^+p\pi^- \) event 2 ns. out of time is 1/50 of the true rate for a beam of \( 10^7 \gamma/sec \). Further, it was assumed that the Level 4 trigger would eliminate one half of these events, and more than 90% of the true \( \gamma p \rightarrow \pi^+p\pi^- \) events. As can be seen from the table, the trigger rates are quite modest.

We have used a file of \( \gamma p \rightarrow \pi^+p\pi^- \) events as input to the FASTMC program to estimate the number of reconstructed \( \Lambda \)'s and \( \Lambda \)'s due to \( \pi^+ \)'s which are misidentified as kaons. For the small sample run to date, (equivalent to about one hour of beam time, for \( N_\gamma = 10^7 \gamma/sec \) only 20 events survived the mass cuts and the trigger Level 3 cuts. No events satisfied the photon missing mass cuts. Further simulation is needed to verify this result.

### IV. Beam Time Request

Setup and calibration will take place during the setup and calibration runs for Ref. 23. These numbers include the usual 50% data-taking efficiency.

- **Trigger studies**: 50 hours
- \( E_\gamma = 3.2 \text{ GeV} \): 200 hours
- \( E_\gamma = 2.4 \text{ GeV} \): 1000 hours

The count rates shown in Table Va indicate that although 100 hours of running at \( E_\gamma = 3.2 \text{ GeV} \) would give a good measurement of the \( \Lambda(1520) \rightarrow \gamma\Lambda \) branching ratio, little else would be measured. Therefore we will assume that the count rate has been increased a factor of five by moving the target upstream and increasing the beam to \( 3 \times 10^7 \gamma/sec \). As mentioned earlier this may require a fast vertex detector to reduce the
accidentals. This target position will also be compatible with Ref. 23. Then 100 hours of running at 3.2 GeV and 500 hours running at 2.4 GeV, will give the measurement shown in Table Vb. Additional data on the Λ(1405) and Σ⁰(1385) branching ratios may be collected as an alternate trigger during the running of the "Electromagnetic Production of Hyperons" experiment. However, they will be running at a lower energy, 1.8 GeV, which will give low count rates for the radiative decay measurement. We assume that the shower counter will have been calibrated in earlier experiments and that this information will be available at beam time.

Further studies on the feasibility of increasing the γ Σ⁰ branching ratio signal thru the use of small, good energy backangle photon detector will continue.

V. Equipment Request

This experiment would require the following resources from CEBAF

1. Tagged photon beam
   Flux $1 - 3 \times 10^7 \gamma/sec$
   Energy resolution $\Delta E_\gamma/E_\gamma = 0.25\% FWHM$ for a 20% energy bite

2. LAS Spectrometer as proposed in CDR

3. Shower Counter with at least 45⁰ coverage. (90⁰ coverage preferable).

4. Liquid hydrogen target 15 cm long, thin walled.

5. Data acquisition system as proposed in the CDR

Possible equipment to be provided by the experimenters

1. Scintillating fiber vertex detector.

2. Small good energy resolution back angle photon detector.

VI. Collaboration

Rice University and The College of William and Mary will take primary responsibility for this phase of the hyperon experiments. Although this proposal has not been joined with that of Carnegie Mellon University, Catholic University of America, Los Alamos National Laboratory, Virginia Polytechnic Institute and State University, CE-
BAF, and Florida State University group's proposal, "Electromagnetic Production of Hyperons," (R. Schumacher, Spokesman), it is clearly in the interests of our group to do so in the near future.

APPENDIX

HYPERON DECAYS

by

T. Goldman, M. V. Hynes, R. E. Mischke, and T. Oka
Los Alamos National Laboratory

T. V. L. Sanford
Sandia National Laboratory

Just as LAMPF has permitted new levels of precision in investigations involving pions and muons, LAMPF II will facilitate such progress above the threshold for production of particles with strangeness. While the strange mesons may receive most attention from particle physicists, the strange baryons also provide essential input to the search for a complete description of subatomic physics.

To keep the discussion of hyperon decays together, some topics in strong-interaction physics are included in addition to those relevant to electroweak physics. Hyperon-nucleon interactions are discussed in a separate section of this document.

I. PRODUCTION OF HYPERONS

The high fluxes of mesons at LAMPF II will favor hyperon production by p's and K's over that by the primary proton beam. The strong-interaction physics to be learned from the production mechanism will involve both kinds of beams. Particularly interesting has been the discovery of polarization of hyperons produced with moderate transverse momentum. The data show that $\Lambda^+$'s, $\Lambda^-$'s, and $\Xi^-$'s are polarized and $\Sigma^+$ are produced polarized with the opposite sign. $\Lambda$'s are unpolarized. The polarization versus transverse momentum is basically independent of target and incident energy (for comparable Feynman $x$ values).

These data have had considerable impact on models of hyperon production. For instance, thermodynamic models do not predict polarization, and in QCD models with many contributing diagrams polarization is unlikely. Quark models have had some success in describing the observations and a next generation of experiments will provide input for refining these models. While the region of highest transverse momentum will be probed at Fermilab, systematic experiments at lower energies will be very important. At LAMPF II energies, final-state multiplicities are manageable, which will facilitate the study of exclusive channels.

II. HYPERON STRUCTURE

Many of the hyperon ground-state properties have been measured already to good precision at existing facilities. Indeed, even the excited-state spectra of the $\Lambda$, $\Sigma$, and $\Xi$ have been known for some time. Yet the crucial data addressing the issue of hyperon structure in terms of the quark model are missing. The status of our understanding of baryon structure in general and hyperon structure in particular is similar in many ways to early developing stages of the nuclear shell model (about 1950). At that time there was an abundance of models each equally successful in reproducing the ground-state properties and excited-state spectra of nuclei. Yet each model made very different predictions for the structure present in these states. The same diversity in structure is present today in the various quark model predictions for the baryons. Just as in nuclei, measurements of electromagnetic decays of baryon excited states will test our quark model understanding with the high precision unique to electromagnetic processes.

In a simple three-quark model ($q^3$), the ground states of the $\Lambda$, $\Sigma$, and $\Xi$ have up, down, and
strange quarks in the \( S1/2 \) orbit. The light quarks (up and down) are coupled to total spin-isospin \( S = 0 \), \( T = 0 \) for the \( A \) and to \( S = 1 \), \( T = 1 \) for the \( \Xi \) as displayed in Fig. 1. The remaining \( S = -1 \) even-parity state, \( \Xi^{+}(1365)/2^+ \), has the strange quark spin aligned with the \( S = 1 \), \( T = 1 \) light quarks (Fig. 1). The ground and excited states of the \( \Xi \) have two strange quarks in the \( S1/2 \) orbit coupled to \( S = 1 \) as shown in Fig. 2. For the ground state the remaining light quark is in the \( S1/2 \) orbit coupled to give \( S = 1/2 \), \( T = 1/2 \), whereas for the excited state it is coupled to give \( S = 3/2 \), \( T = 1/2 \).

The odd-parity states, \( A^+(1405)/1^- \) and \( A^+(1520)/3/2^- \), have one quark in the \( P1/2 \) and \( P3/2 \) orbits, respectively. DeGrand and Jaffe have pointed out that the kinetic energy for the \( 1^- \) state is considerably lower if the strange quark, rather than one of the light quarks, is placed in the \( P1/2 \) level. Thus the \( q^3 \) \( 1/2 \) configuration for the \( A^+(1405)/1^- \) state consists of the light quarks in \( S1/2 \) coupled to \( S = 0 \), \( T = 0 \), and the strange quark in the \( P1/2 \) orbit as shown in Fig. 1. This configuration requires that any radiative transition from this state to a pure, strange quark \( P1/2 \rightarrow S1/2 \) transition. Because the electromagnetic operators can change the quantum numbers of only one particle, the radiative widths for \( A^+(1405) \rightarrow \pi^0(1193)\gamma \) or \( \Xi^+(1385)\gamma \), are strictly zero.

The simplest \( q^3 \) configuration assumption for the \( A^+(1520)/3/2^- \) has the strange quark in the \( P3/2 \) state with the light quarks coupled to \( S = 0 \), \( T = 0 \). However, gluon exchange calculations by DeGrand and others indicate a sizable admixture of light quark occupation in the \( P3/2 \) orbit with the remaining quarks in \( S1/2 \) coupled to \( S = 0 \), \( T = 0 \), as shown in Fig. 1. In the notation of DeGrand, the \( A^+(1520)/3/2^- \) wave function is written as

\[
A^+(1520)/3/2^- = a \hat{4}A + b \hat{2}A + c \hat{1} \]

\[
|a|^2 + |b|^2 + |c|^2 = 1 .
\]
where $^{15+1}_2$ means the SU(3) flavor multiplet $\sigma$ with total spin $S$. DeGrand finds $a = 0.85$, $b = 0.51$, $c = 0.1$, indicating a predominance of singlet and octet configurations as already discussed. The $^3\Lambda$ component corresponds to having one quark in the $\Phi/2$ orbit, the two $S$-state quarks coupled to $S = 1$, and the system coupled to $3/2^+$. Other gluon exchange calculations find similar admixture coefficients with smaller $^3\Lambda$ contributions, however. If the small $^3\Lambda$ admixtures are ignored, the wave function is as shown in Fig. 5. This configuration and the one-body nature of the electromagnetic operators implies that the radiative width for the transition $\Lambda^s(1520) - \Lambda^s(1585)^+$ is zero. We have therefore in the pure $q^3$ model three forbidden radiative transitions $\Lambda^s(1405) = \Lambda^s(1520)$, $\Lambda^s(1585)^+$, and $\Lambda^s(1520) - \Lambda^s(1585)^+$ due to this selection rule.

There is an additional selection rule that enters for some of the transitions of interest here. The SU(3) classification scheme places the ground states of $\Sigma$ and $\Xi$ in the $1/2^+$ baryon octet whereas their first excited states, $\Sigma^*(1385)$ and $\Xi^*(1530)$, are members of the $3/2^+$ baryon decuplet as displayed in Fig. 5. In this figure $c_3$ is plotted versus hypercharge with $U$-spin, $V$-spin, and $W$-spin axes. In pure SU(3), $U$-spin and $V$-spin are invariants. Thus the $\Sigma^*$ and $\Xi^*$ being in a $U$-spin quartet cannot decay through a $U$-spin scalar interaction to their respective ground states, which are in a $U$-spin doublet. The photon transforms as a $U$-spin scalar and thus the electromagnetic decay of these states to their ground states is forbidden. In contrast, the electromagnetic decays of the $\Sigma^0$, $\Sigma^+$, and $\Xi^0$ to their respective ground states do not violate $U$ spin and are thus allowed.

SU(3) is, of course, a broken symmetry and it is precisely the symmetry breaking that splits the masses of the members of a multiplet. Thus when the constituent quarks are allowed to have different masses, the strange quark being heavier than the nonstrange ones, the forbidden transition just cited becomes allowed. The electromagnetic transition amplitudes will be proportional to the difference between the strange- and down-quark masses.

The remaining allowed widths can be calculated straightforwardly from the quark wave functions:

$$u_\tau = 2\kappa \left[ \frac{1}{2s^2 + 1} \right]$$

$$\frac{1}{2} \sum_{\lambda} \langle \ell, m_\ell | \mathcal{L}_{\ell}^\tau | \ell, m_\ell \rangle^2$$

where $\ell = 0, 1 \equiv 21$. 

---

Fig. 4. Quark-level occupation diagrams for the $\Lambda^s(1520)$ in the $q^3$ model. Both singlet and octet configurations are shown.

Fig. 5. $c_3$ versus hypercharge display of the SU(3) baryon octet and decuplet. The $U$, $V$, and $W$-spin axes are as shown.
In this expression the current operator is given by

\[ j = e_q r^{1/2} \]

with \( e_q \) the charge of the quark with flavor \( f \); \( r^{1/2} \) is the photon momentum; \( F(Y) \) is the initial (final) quark wave function; and \( a \) is the usual electromagnetic propagator. Nonis, Soyeur, and Kaxiras have calculated the allowed radiative widths for the neutral \( s = -1 \) states of interest in the context of the fixed radius, static cavity approximation to the MIT bag model. Their results for the pure \( q^3 \) wave functions are listed in Table I. Also listed in the table are the results of T. Kaxiras, who has calculated these widths in the context of the Isgur-Karl (IK) model.\(^6\) In this model two sets of basis states were used. In the "SU(6)" basis the spin-isospin wave functions are symmetrized in all three quarks and they are given in the limit of equal masses. The transition widths are calculated, however, with differing quark masses. In the "uda" basis, the wave functions are symmetrized only with respect to the \( u \) and \( d \) quarks. The strange- and nonstrange-quark masses are treated as before. The results in these two cases are listed in the appropriate columns in the table. Evidently the three different predictions differ by as much as a factor of 60. In addition, some of the transitions forbidden in the MIT bag are allowed in the IK model.

The assumption of pure \( q^3 \) configurations for these states has recently been brought into question by Haiders, who calculated the importance of \( q^4 \) admixtures for the \( A^*(1405) \). In this work the quarks for the \( q^4 \) configuration were taken to be in the \( 3/2^- \) orbit and the \( q^3 \) configuration was taken to be as shown in Fig. 1. Using a simple two-state mixing model, an estimate of the relative strengths was obtained.

\[ A^*(1405) = 0.8 |q^3\rangle + 0.6 |q^4\rangle \]

Such a large \( q^4 \) admixture for the \( A^*(1405) \) considerably alters the results listed in Table I. In particular, the \( A^*(1405) \to \pi^0 \gamma \gamma \) transition rates are no longer zero. Nonis and Soyeur have calculated the effect of including these \( q^4 \) admixtures on the radiative widths by using the results of Brottman for the \( q^4 \) components in the \( A \) and \( I \) ground states.\(^7\) These results and their estimates for such admixtures in the \( A^*(1405) \) state are listed in Table II. Because the relative phase of the \( q^4 \) and \( q^3 \) contributions is not known, the table displays the results for destructive and constructive interference. The \( A^*(1405) \) radiative

\(^*\) F. Haiders, MIT, private communications.
decay to the 2 ground state has no q^3 component and

go only through the q^-q admixtures.

The available electromagnetic data on the

states of interest here is quite sparse. The

Q^0(1113) decays 100% to A^0(1116)Y and has been

measured by Dyak et al. 8 to be 11.5 ± 1.6 keV. In

this experiment a 20-GeV A beam at the CERN SPS was

incident on a uranium target. The Primakoff effect

was used to produce Q^0's in the inverse reaction

A + Y = Q^0. This value does not compare well with

the MIT bag model calculation, which predicts

4.5 keV or about four times smaller. This is not

too surprising as the same model predicts 225 keV

for the A + Y radiative width whereas the

experimental value is 430 keV. The reasons for

these discrepancies are not understood. The static

bag approximation neglects recoil, which will alter

the theoretical predictions, but no estimate of the

changed values is available. The J = 0 predictions,

8.4 and 8.9 keV, are about 10% low for

this transition.

There exists one measurement 9 of the

A^0(1320) = A^0(1116)Y. However, to obtain the radiative

width, an appreciable Q^0 background subtraction

was made assuming that the A^0(1320) is an

SU(3) singlet. Such a model-dependent subtraction

severely compromises the utility of this measure-

ment. Lastly, there are upper bounds on the

Q^0(1385) radiative decay widths. 

The low-lying excited states of the S = 1, -2

baryons provide a very useful laboratory in which

to study quark confinement models. The spectrum

includes both positive- and negative-parity states.

The positive-parity states and their interconnect-

ing transitions allow for tests of the 5-state wave

functions and quark magnetic moments. In addition

ey may allow for tests of possible quadrupole de-

formations through the presence of E2 components

in the transitions. The negative-parity states and

their transitions provide a different test of quark

wave functions, one in which the orbital quantum

number of at least one quark must be changed.

Finally, due to their very narrow widths, the

strange-resonance excited states are ideal probes

for the study of resonance propagation in nuclei.

In particular a comparison of the free-space elec-

tromagnetic decays with those occurring in a

nuclear medium will provide important information

on the medium-modifications to confinement. A

experimental determination of these radiative tr-

sition widths benchmarks in free space and in the nucl

medium will illuminate the quark structure of the

states in particular and can help to direct the

development of quark confinement models in general

III. HYPERON DECAYS

A. Semileptonic Hyperon Decays

An understanding of weak interactions beve

quarks will come from the dynamics of high-energy

collisions and from the systematics of bound

states. Semileptonic decays of baryons play a c

sential role in testing quark models. The present

situation can be summarized by observing the suc-

cess of the Cabibbo theory in general, but noting

several important disagreements that indicate

challenges for theorists. It is likely a succes-

sive approximation technique will be used— as

experiments improve, more sophisticated models

will be required until, at some point, a "correct"

theory will emerge.

The comparison between theory and experiment

is usually made via the six form factors that ap-

pear in the general form of the hadronic weak cur-

rent. For semileptonic hyperon decay the Hamil-

tonian is given by

\[ R_\mu = \sum \frac{G}{\sqrt{2}} \mathbf{J}_j \mathbf{L}_j \mu + \text{h.c.} \]

where \( G = 10^{-3}/\alpha_0^2 \) is the usual weak-coupling con-

stant,

\[ \mathbf{J}_j = \bar{\nu}_\mu \gamma_5 (1 + \gamma_5) \mathbf{Y}_j \]

is the lepton current, and

\[ \mathbf{L}_j = \cos \theta_1 \mathbf{Y}_j (1 + \gamma_5) \]

\[ + \sin \theta_2 \cos \theta_3 \mathbf{Y}_3 (1 + \gamma_5) \]

is the hadronic current. The angles \( \theta_1 \) and \( \theta_3 \) are

from the Kobayashi-Maskawa form of the quark mixing

matrix. \( \theta_2 \) These angles must be determined from ex-

periments.

The matrix element of the hadronic current be-

tween hadrons in the decay A - B\ kappa is given by
\[
\langle B | J_1 | A \rangle = \left( \frac{\cos \theta_1}{\sin \theta_1 \cos \delta_0} \right) \bar{u}_b \left[ t_1(q^2) \gamma_\lambda - \frac{1}{m_a + m_b} \alpha_0 \eta \beta_0 \gamma_\lambda + t_2(q^2)q_\lambda - \frac{1}{m_a + m_b} \alpha_0 \eta \beta_0 \gamma_\lambda \right] u_a.
\]

All the form factors are relatively real by T invariance. The terms \(t_3\) and \(g_3\) vanish by C-parity invariance and SU(3) symmetry. The \(g_3\) term is related to \(g_1\) by the Goldberger-Treiman relation and for \(q^2 = 0\) the relation is given by

\[
g_3(0) = \frac{2m_0(m_a + m_b)}{m_b^2} g_1(0).
\]

This relation has not been tested by the decay, because \(g_3\) term is multiplied by a factor \((m_a/m_b)^2\) and negligible in the electronic decay modes. However, we can expect larger effect in the muonic decay modes. For example, the decay rate \(A = \mu \mu\) is expressed

\[
\Gamma = \frac{\Gamma_1(0)}{1 + 0.025e} + 0.00907 f_4(0) f_2(0) + 2.486 \, g_1^2(0) (1 + 0.0468) + 0.427 g_1(0) g_2(0) + 0.00093 g_1(0) g_3(0)
\]

where

\[
\frac{\Gamma_1(0)}{\Gamma_1(0)} = \frac{g_1^2(0) \sin^2 \theta \cos^2 \delta_0}{128} = 2.3342 \times 10^{-4}.
\]

The parameters \(a\) and \(r\) are defined as \(f_1(q^2) = f_1(0)(1 + a q^2/(m_a + m_b)^2)\) and \(g_1(q^2) = g_1(0)(1 + r q^2/(m_a + m_b)^2)\), respectively.

Using the SU(3) relation for form factors, \(a = 9, r = 5\), and recently obtained values for \(F\) and \(D\), that is, \(f_1(0) = -1.1, f_2(0) = -\sqrt{72} 2 p,\) and \(g_1(0) = -2(3F + D)/3 \approx 0.865\), the ratio of \(\Gamma_1(q^2)/\Gamma_1(0)\) is

\[
\frac{\Gamma_1(q^2)}{\Gamma_1(0)} = 0.008.
\]

This value may be too small to obtain the information about \(g_3\) term even in the muonic decay modes. This leaves \(f_1, g_1,\) and \(f_2\) as the most likely to be significant.

The experimentally determined quantities are the decay rate \(\Gamma\) and angular-correlation coefficients. The lepton-neutrino angular correlation \(\alpha_{\nu\nu}\) (deduced from the nucleon energy spectrum) and \(\alpha_{\nu p}\) do not require polarized hyperons, but \(\alpha_{\nu p}\) measures the correlation with the hyperon spin direction.

Explicit expressions can be written to relate \(\Gamma\) and the \(a\) 's to \(f_1, g_1,\) and \(f_2\). Experimentally, the decay rate for \(\Lambda = \beta p\) is related to \(f_1\) and \(g_1\) by

\[
\Gamma = \frac{G_a^2 \sin^2 \theta \alpha_{\nu\nu}^2}{60 m^2} (f_1^2 + 3g_1^2)(1 - \delta)
\]

where \(\alpha_{\nu\nu} = \Lambda - \Lambda_0\) and only terms up to first order in \(\delta\)

\[
\delta = \frac{\alpha_{\nu\nu}}{m_a + m_b}
\]

have been kept. In addition to the rate, the magnitude of \(g_1/f_1\) is related to the lepton-neutrino correlation coefficient \(\alpha_{\nu\nu}\) by

\[
\alpha_{\nu\nu} = \frac{f_1^2 - g_1^2}{f_1^2 + 3g_1^2} = 26
\]

in \(U(\cos \theta_{\nu\nu}) = (1 + \alpha_{\nu\nu} \cos \theta_{\nu\nu})/2\). The sign of \(g_1/f_1\) can be extracted from the correlation between the directions of the decay particles.
\[
\begin{align*}
\alpha &= \frac{2(\ell_1 \ell_2^* - \ell_1^2 - \frac{1}{3}[2(\ell_1 + \ell_2)^2 + 2\ell_2(\ell_1 + \ell_2)]}{\ell_1^2 + 3\ell_2^2} \\
\alpha_y &= \frac{2(\ell_1 \ell_2^* + \ell_1^2) - \frac{1}{3}[2(\ell_1 - \ell_2)^2 + 2\ell_2(\ell_1 - \ell_2)]}{\ell_1^2 + 3\ell_2^2} \\
\alpha_p &= \frac{-\frac{5}{2} \ell_1 \ell_2^* + \frac{4}{3} [2(\ell_1 - \ell_2) \ell_2]}{\ell_1^2 + 3\ell_2^2}
\end{align*}
\]

\(f_1(\ell_2) = 1/2(1 + \alpha \bar{p} \cdot \ell_2)\) for polarized hyperons. \(\bar{p}_y\) is the hyperon polarization and \(\bar{q}\) is the direction of the decay baryon.

It is also possible to specify \(f_1\) and \(f_2\) in terms of the electromagnetic form factors of the neutron and proton using the conserved-vector-current hypothesis. Then \(f_1\) and \(f_2\) are given by Clebsch-Gordan coefficients and the anomalous magnetic moments of the neutron and proton. Then \(f_1\) is expressed in terms of unknown SU(3) reduced form factors, \(F\) and \(D\). Recently, Garcia and Kiehn13 have fit all hyperon semileptonic data to this model with \(F\), \(D\), and \(\ell_2^*\) as parameters. They assume the simpler Cabibbo theory, which just sets \(\ell_2^* = 0\). It is found that including radiative corrections and the \(q^2\) dependence of the leading form factors makes a significant improvement in the fit. Even so, a few pieces of experimental data refuse to fit. Most notable is the electron asymmetry in \(\Sigma^-\) decay. The sign of the ratio \(g_1/g_2\) is opposite that predicted by the Cabibbo model.

Only precise data on semileptonic hyperon decays will produce significant advances in theoretical understanding. It is clear that approximate SU(3) symmetry is valid and the gross features of the data are mostly catalogued. But a real theory needs to describe the symmetry-breaking effects in detail or even alternative symmetries. For example, the possibility that a left-right symmetric theory will fit the data is being investigated.

\section{Nonleptonic Decays}

Nonleptonic decays such as
\[
\Lambda \to p\pi^0 \\
\Sigma^- \to n\pi^-
\]
are used to test the \(\Delta I = 1/2\) rule and other QCD predictions.

They are transitions where the final-state baryon-antibaryon pair can be in either a \(I = 0\) or \(I = 1\) state. Let \(s\) and \(p\) be the parity-changing \((I = 0)\) and parity-conserving \((I = 1)\) amplitudes, respectively. Then the transition matrix for hyperon decay is\(^{15}\) \(M = s + p(\vec{\ell} \cdot \vec{q})\). Here \(\vec{q}\) is the unit vector along the direction of the decay baryon in the hyperon rest-frame. For hadronic collisions like \(\nu p \to \Sigma^- k^+\) the hyperon is polarized perpendicular to the plane of interaction.\(^{15}\) For such a situation \(s\) and \(p\) are related to the asymmetry parameter \(\alpha\) via
\[
\alpha = \frac{2Re(s^* p)}{|s^* p| (1 + 2s^* p)}
\]
in the angular distribution of the decay baryon in the hyperon frame: \(I = 1 + \alpha \bar{p}_y \cdot \bar{q}\). Again \(\bar{p}_y\) is the hyperon polarization.

The asymmetry parameter has been measured for many hadronic decay channels. However, the \(Q^-\) is difficult to produce so that \(\alpha\) is poorly known for its various decay modes. For example, Nemevsky\(^{16}\) measured \(\alpha = -0.2 \pm 0.4\) for \(Q^- \to \Lambda K^-\) decay. The result is in agreement with the calculation of Finkelnburg,\(^{17}\) who expects the decay to be nearly parity conserving. Statistics are weak, however, so much could be learned by increased \(Q^-\) production at FNAL II.

Nourai measured\(^{18}\)
\[
\frac{\Gamma(Q^- \to \Xi^- K^-)}{\Gamma(Q^- \to \Sigma^- n)} = 2.94 \pm 0.33
\]
for the decuplet-octet transition. Because the \(Q^-\) contains three strange quarks, the \(\Delta I = 1/2\) amplitude is expected to be 20% of the \(\Delta I = 1/2\) amplitude,\(^{19}\) giving
\[
\frac{\Gamma(Q^- \to \Xi^- K^-)}{\Gamma(Q^- \to \Sigma^- n)} = 3 \pm 0.3
\]
in agreement with experiment.

Improvements in experiment are necessary before a test of one of the proton's zeroes of the standard model of the strong and electroweak

\[125\]
interactions can be made. This is the beginning of a dynamical understanding of the $\Delta = 1/2$ rule in nonleptonic hyperon and kaon decays. The effective weak-interaction Hamiltonian for quarks is not that given by the GWS model alone. Finite, calculable (in principle) effects are induced by gluon exchanges. These come in two forms: initial- and final-state, etc., interactions as indicated in Fig. 6 and also "penguin" effects, such as shown in Fig. 7. The latter have no physical effects when the strong interactions are absent, as they can be absorbed into a weak-interaction wave-function renormalization of the quarks. Because of the vectorial coupling of the gluon, these penguin graphs induce effective nonleptonic right-handed charged-current interactions as well as effective strangeness-changing neutral-current interactions.

We say these calculations are precursors as they indicate enhancement of $\Delta = 1/2$ processes. Unfortunately, these "short distance" calculations do not show sufficient relative (to $\Delta = 1/2$) enhancement to explain the data. This alone may not be too unsatisfactory as there are additional "long distance" (current algebra) pieces that have not been included. However, there are reasons to question even the magnitude of the short distance enhancements. Explicit one-loop calculations show that there may be significant emissions in the more popular "leading logarithms approximation" (or Operator Product Expansion) calculations.

Nonetheless, this is an active area of theoretical effort. If more detailed information on decay channels (final-state polarizations would be very important) could be obtained, many of the ambiguities might be resolved phenomenologically. Because they involve the dynamical interplay of the strong and weak interactions beyond the level of tree graphs, studies in this area offer deep tests of the full quantum field theory of the standard model.

C. Radiative Decays

The radiative decays $\pi^+ \to \nu$, $\pi^0 \to \gamma\nu$, $\pi^\pm \to \nu\gamma$, $\pi^0 \to \gamma\pi^\pm$, and $\pi^0 \to \pi^\pm\gamma$ are used to test QCD calculations (see Sec. II) and are sensitive to the contribution the penguin diagram makes to the process.

The decays fall into the general class of decays $B_1(P_1) = B_2(P_2) \to \gamma(k)$

$$k = P_1 - P_2$$

which are described by the transition matrix

$$M = E_{\nu}(k)\bar{\nu}(P_2)[a + bv_3]g_{\mu\nu}k_{\mu}U(P_1)$$

$E_{\nu}$ is the photon polarization, and $a$ and $b$ are the parity-conserving and parity-violating amplitudes, respectively. The amplitudes can be estimated by QCD calculations. They are related to the decay rate $\Gamma$ and asymmetry parameter $\alpha$ by the equations

$$\Gamma = \frac{1}{r} \left( \frac{n_1^2 + n_2^2}{2n_1} \right) (|a|^2 + |b|^2)$$

$$\alpha = \frac{2\text{Re}(a\ast b)}{|a|^2 + |b|^2}$$

In the exact SU(3) limit assuming CP invariance, $G$-spin symmetry, and a current-current form of the weak interaction involving only left-handed currents, $\alpha$ is predicted to be zero. Strong-interaction effects can be included via current algebra calculations and yield predictions typically about $\alpha = -0.25$ (Refs. 24, 25).

Other calculations to determine strong interaction effects employing dispersion relations to evaluate contributions of $\pi$ intermediate states have results ranging from $-1.0$ (Ref. 26) to +0.8 (Ref. 27) depending on input parameters. Theoretical reasons have been presented that rule against such large values of $\alpha$ from strong interactions and most predictions favor smaller values.

Recently two papers have been independently published which predict a large asymmetry, $\alpha = -1$, as a result of a right-handed current between the charm and strange quarks. Such currents have been suggested to explain the nonleptonic $\Delta = 1/2$ rule and the large ratio of nonleptonic to semileptonic weak decays. Present high-energy neutrino data, most notably the $\nu \nu$ dependence of the reaction $\nu N \to u \bar{\nu}x$ and the large ratio $\sigma(\nu N \to u \bar{\nu}x)/\sigma(\nu N \to u \bar{\nu}x)$, are indicative of right-handed currents between the usual quarks and a heavier object. Thus, there seems to be evidence
Fig. 6. Gluon exchange corrections for weak processes.

Fig. 7. Penguin diagram contribution to strangeness-changing processes.

\[ q \rightarrow W \rightarrow W\]  
\[ s \rightarrow u(c) \rightarrow d\]
\[ q \rightarrow g \rightarrow g\]

This result is based on 61 events.

The value of \( a \) has been taken on new significance as a result of the above ideas. The statistical quality and systematic uncertainty involved in the present measured value are quite poor. Because \( a \) is a fundamental and interesting parameter in the theory on the radiative decay of the \( \Xi^+ \) hyperon, a new measurement with good statistics and the feature of small systematic error inherent in polarized target experiments is needed.

Within the framework of QCD the three types of quark diagrams shown in Fig. 6 are believed to contribute to the direct radiative decay. The four-quark diagram, not allowed for \( \Xi^0 \) or \( \Xi^+ \) decays, is allowed for \( \Xi^0 \) decay. A comparison of \( \Xi^0 \) decay with \( \Xi^+ \) and \( \Xi^- \) decay then allows the four-quark diagram to be isolated. This type of analysis is being proposed by K. Foster at BNL using the Medium-Energy Separated Beam in conjunction with the Multiparticle Spectrometer.\(^{12}\) Even assuming that the experiment of K. Foster is run, it is evident from Table III that LAMPF II can be used to make a substantial impact on the understanding of these decays.

D. Suppressed or Forbidden Decays

The increase of cleanly tagged hyperon anticipated at LAMPF II can be used to improve limits on a multitude of suppressed or forbidden decays. The following provides a list and discussion of a few possibilities together with current experimental limits.

1. Strangeness-Changing Neutral-Current Transitions. Strangeness-changing neutral-currents are suppressed by the GIM cancellation mechanism. Like kaon decays,\(^{16}\) hyperon decays that involve such currents should exist in second-order in the electroweak interaction and be calculable in any renormalizable gauge theory.

A limit of

\[ \frac{\Gamma(\Xi^+ \rightarrow p\pi^+)}{\Gamma(\Xi^+ \rightarrow all)} < 7 \times 10^{-6} \]

for such a process is given by Ang using a bubble chamber with a stopped-\( K^\pi \) beam.\(^{17}\)

2. \( \Delta S = 2 \) Transitions. No decay that violates the (\( \Delta S = 1 \)) rule in first-order electroweak interaction is known to exist. Searches for such processes consequently are of fundamental importance.

The \( \Delta S = 2 \) transition \( \Xi^0 \rightarrow p\pi^0 \) was looked for by Coweniger et al.,\(^{18}\) using the CEBAF neutral-hyperon beam. They set the limit

$^a$Upper limits are at 90% confidence level as listed in Particle Data Group, Phys. Lett. 73B, 1 (1978).

\[
\frac{\Gamma(\Sigma^0 \to \pi^+ \gamma)}{\Gamma(\Sigma^0 \to \Lambda \gamma)} < 1.3 \times 10^{-3}
\]

Similarly, Bourquin in the CERN charged-hyperon beam set the limit\(^{18}\)

\[
\frac{\Gamma(\Sigma^0 \to \Lambda \gamma)}{\Gamma(\Sigma^0 \to \Lambda \gamma)} < 1.3 \times 10^{-3}
\]

for $\Lambda$ decay.

3. **Flavor-Changing Neutral-Current Transitions.** Flavor-changing neutral-current transitions are sensitive to new interactions that are expected from horizontal-symmetry models that relate generations.\(^{16}\) Kane and Tuan\(^{19}\) comment that a search for such a process in $\Sigma^+$ decay may have advantages over such a search in known decay because the decay does not require a coupling to a pseudoscalar current, which would be sensitive to helicity suppression. However, the limit on the possible branching ratio for $\Sigma^+ \to \Lambda \gamma$ decay they set for such a process, based on the $\Sigma^+ - \Sigma^0$ mass difference and the current $\Sigma^+ \to \Lambda \gamma$ branching ratio, is only $BR(\Sigma^+ \to \Lambda \gamma) < 10^{-12}$. Obviously, to observe such a decay, clean and intense $\Sigma^+$ fluxes are needed as will be obtainable at LAMPF II.

Proposal Number: PR-89-024

Proposal Title: Radiative Decays of the Low-Lying Hyperons

Spokespersons/Contact Persons: G. Mutchler

Proposal Status at CEBAF:

The A7 measurement may be carried out to the extent feasible in conjunction with the approved running of PR-89-004, the latter experiment being the primary determinant of running conditions. For the E7 work deferral is recommended.

John Dirk Walecka
Scientific Director
October 31, 1989

Professor John Dirk Walecka
Scientific Director, CEBAF
12070 Jefferson Avenue
Newport News, Virginia 23606

Dear Professor Walecka:

Enclosed is our proposal "Radiative Decays of the Low Lying Hyperons," using the LAS. This proposal should be considered in conjunction with the proposal "Electromagnetic Production of Hyperons" R. Schumacher, Spokesman.

Sincerely,

[Signature]

G. S. Mutchler
Professor of Physics

Figure 8: Missing mass spectrum of photon from reaction \( \gamma p \rightarrow K^+ \Lambda(1405), \Sigma(1285) \rightarrow K^+ \gamma \Lambda \)
FIG 2. (a) The experimental spectrum of data from one of the two running periods showing the two signal peaks plus backgrounds discussed in the text. (b) The region of the spectrum containing the $\Sigma\gamma$ signal. The smooth solid curve is the total background; the solid histogram is the fit to the data. The signal contribution to the fit is shown separately at the bottom of the figure. (c) The end-point region of the photon spectrum showing the $\Lambda\gamma$ radiative-capture peak and the end-point region the $x^0$ decay photons from the $\Lambda x^0$ channel. The solid curve is the best fit. The background from $K^-$ decays plus target emulsion shown as a dot-dashed curve, while the contribution from in-flight interactions is shown by a dashed line. The latter are the inelastic contribution above the end point. The $\Lambda\gamma$ signal contribution is shown as a separate dashed line.
