41 **Abstract**

42 The Jefferson Laboratory *PrimEx* Collaboration has developed and imple-  
43 mented a method to control the tagged photon flux in photoproduction experi-  
44 ments at the 1% level over the photon energy range from 4.9 to 5.5 GeV. This  
45 method has been successfully implemented in a high precision measurement of  
46 the neutral pion lifetime. Here, we outline the experimental equipment and the  
47 analysis techniques used to accomplish this. These include the use of a total  
48 absorption counter for absolute flux calibration, a pair spectrometer for online  
49 relative flux monitoring, and a new method for postbremsstrahlung electron  
50 counting.

51 *Keywords:* photon tagging, pair spectrometer, photonuclear reactions

---

## 52 1. Introduction

53 The photon tagging technique has been used routinely in various forms  
54 [1–9] to provide quasimonochromatic photons for absolute photonuclear cross  
55 section measurements. The analysis of such experiments in the context of  
56 bremsstrahlung photon tagging was summarized by Owens in 1990 [10]. Since  
57 then, a number of developments have made possible significant improvements in  
58 the implementation of this technique. Here, we describe the steps taken by the  
59 *PrimEx* Collaboration in Hall B of Jefferson Laboratory to limit the systematic  
60 uncertainty in the absolute photon flux to the 1% level. They include an ab-  
61 solute flux calibration at low intensity with a total absorption counter, online  
62 relative flux monitoring with a pair spectrometer, and the use of multi-hit time  
63 to digital converters for post bremsstrahlung electron counting during produc-  
64 tion data runs. While this discussion focuses on the analysis techniques utilized  
65 by the *PrimEx* Collaboration which involves a bremsstrahlung based photon  
66 tagging system to measure the neutral pion lifetime, the methods described  
67 herein readily apply to other types of photon tagging system.

## 68 **2. The *PrimEx* Experimental setup**

69 The goal of the *PrimEx* experiment is to perform a precise measurement of  
70 the cross section for photoproduction of neutral pions in the Coulomb field of  
71 a nucleus (the Primakoff effect)[13]. The primary equipment in the experiment  
72 includes (see Fig. 1): (1) the Hall B photon tagger; (2) solid  $\pi^0$  production  
73 targets (C, Si, and Pb) of thickness 5-10% of a radiation length (r.l.); (3) a  
74 sweeping magnet/pair spectrometer located after the production targets; (4)  
75 a 1.16m  $\times$  1.16m highly segmented lead glass photon detector for  $\pi^0$  decay  
76 photons, with a high resolution  $PbWO_4$  insertion in the central region near the  
77 beam and a plastic scintillator charged particle veto [12].

## 78 **3. Photon tagging in Hall B of Jefferson Lab**

79 Jefferson Lab (JLab) Hall B photon experiments utilize the well known  
80 bremsstrahlung photon tagging technique to measure the energy and time in-  
81 formation of incident photons in real photon induced reactions [9]. The electron  
82 beam of initial energy  $E_0$  (in the case of *PrimEx*  $E_0 = 5.76$  GeV) is incident  
83 upon a thin ( $3 \times 10^{-4}$ ,  $10^{-4}$  or  $10^{-5}$  r.l.) gold bremsstrahlung radiator foil. The  
84 electron loses energy in the electromagnetic field of the nucleus and in the pro-  
85 cess emits a bremsstrahlung photon. The number of photons with energies in  
86 the interval  $k - k + dk$  is approximately proportional to the  $Z^2$  of the radiator  
87 and, over most of the photon energy range, is approximately inversely propor-  
88 tional to the energy  $k$  of the photons [14]. Due to the relatively small mass of  
89 the electron the recoil energy transferred to the nucleus is negligible, and the  
90 bremsstrahlung photon energy can be written as:

$$E_\gamma = E_0 - E_e \tag{1}$$

91 where  $E_\gamma$  is the energy of the bremsstrahlung photon and  $E_e$  is the energy of  
92 the post-bremsstrahlung electron. In the case of Hall B of Jefferson Laboratory,  
93 the energy  $E_0$  of the electrons incident on the radiator is determined at the

Figure 1: Layout of the *PrimEx* experimental setup.

94  $10^{-4}$  level by their trajectories through the arc magnets of the accelerator[15].  
 95 Thus, one can determine the energy of the photon by measuring the energy of  
 96 the post-bremsstrahlung electron.

97 The main components of the Jefferson Lab Hall B photon tagger are a thin  
 98 bremsstrahlung radiator, a dipole magnet capable of a full field of 1.75 T and two  
 99 rows of plastic scintillator hodoscopes. The photons produced in the radiator  
 100 continue through the tagger, toward the physics target 7.1 meters downstream  
 101 in the experimental hall. For the *PrimEx* experiment, a 12.7 mm diameter  
 102 clean-up collimator placed 6.6 meters from the radiator in conjunction with a

103 0.73 T permanent magnet are centered on the photon beam line in order to  
104 limit the transverse extent of the photon beam. Post bremsstrahlung electrons  
105 are separated from the photons by the tagger dipole magnet. The field setting  
106 of the magnet is adjusted according to the incident beam energy to allow full  
107 energy electrons which do not interact in the radiator to be transported into  
108 a shielded beam dump below the floor of the experimental hall. The energy-  
109 degraded electrons are detected in E-counters (for energy determination) and  
110 T- counters (for timing) that lie along a flat focal plane downstream from the  
111 straight edge of the magnet as described in reference [9].

112 The focal plane of the tagger is divided into two groups of T-counters. The  
113 first group of 19 counters covers the photon energy range from 77% to 95% of the  
114 incident electron energy, and the group of 42 remaining wider counters covers  
115 the range from 20% to 77%. The size of individual T-counters compensates  
116 for the  $1/k$  behavior of the bremsstrahlung cross-section. The width of each  
117 T-counter is chosen in such a fashion that it enables approximately the same  
118 counting rate for each detector within the same group. When all 61 T-counters  
119 are used, the total tagging rate can be as high as 50 MHz for the whole focal  
120 plane. The high energy photon counters T1-T19 are proportionally smaller,  
121 and allow a tagging rate of up to 50 MHz in this region alone [9]. The *PrimEx*  
122 experiment used only the counters T1 (corresponding to  $E_\gamma = 5.5$  GeV) through  
123 T11 ( $E_\gamma = 4.9$  GeV).

124 The use of the Jefferson Lab Hall B photon tagging facility gives the *PrimEx*  
125 experiment several advantages over the previous experiments that were based  
126 on the Primakoff effect [16–20]. The angular dependence of the  $\pi^0$  photoproduc-  
127 tion cross section being measured is strongly dependent on the incident photon  
128 energy. The precise determination of the tagged photon flux on the experimen-  
129 tal target is also enabled by the tagger. Thus a more accurate knowledge and  
130 control of the photon beam energy and the luminosity enables a greater control  
131 over systematic errors.

132 In order to determine the energy of the  $\pi^0$ , each event is recorded in coinci-  
133 dence with a signal from the tagger. The experimental cross section for neutral

134 pion photoproduction is determined by the following expression:

$$\frac{d\sigma}{d\Omega} = \frac{dY_{\pi^0}^{tagged}}{N_{\gamma}^{tagged} \cdot \epsilon \cdot t \cdot d\Omega} \quad (2)$$

135 where  $d\Omega$  is the element of solid angle of the pion detector,  $dY_{\pi^0}^{tagged}$  is the  
 136 yield of tagged  $\pi^0$ 's within solid angle  $d\Omega$ ,  $t$  is the target thickness,  $\epsilon$  is a  
 137 factor accounting for geometrical acceptance and energy dependent detection  
 138 efficiency, and  $N_{\gamma}^{tagged}$  is the number of tagged photons on the target.

139 As can be seen from Equation 2, the normalization of the cross section  
 140 directly depends on knowing the tagged photon flux on the target. The number  
 141 of tagged photons is not equal to the number of hits recorded by the tagging  
 142 counters because of a number of effects:

143 (1) events in which a bremsstrahlung photon is produced and then absorbed  
 144 before reaching the target.

145 (2) processes, such as Møller scattering in the bremsstrahlung radiator, through  
 146 which the main electron beam generates counts in the tagging counters  
 147 without an accompanying photon.

148 (3) extra hits registered in the tagging counters due to (beam off) room back-  
 149 ground in the experimental hall.

150 To minimize the absorption of photons before they reach the target, the  
 151 bremsstrahlung beam travels in vacuum. The Møller scattering events are  
 152 thought to affect the tagging ratio at the level of a few percent[9]. The im-  
 153 pact of the room background on the tagging rates of runs with various electron  
 154 beam intensities is continuously monitored.

155 The combination of these effects can be measured in a calibration run by  
 156 removing the physics target and placing a large acceptance lead-glass Total Ab-  
 157 sorption Counter (TAC) directly in the photon beam. Assuming that the total  
 158 absorption counter is 100% efficient in detecting photons in the energy range  
 159 relevant for the experiment (a GEANT simulation gave 99.97% efficiency for

160 4.6 GeV photons with a 1.1 GeV threshold), the ratio of Tagger-TAC coinci-  
 161 dences to the number of tagger hits, the so called absolute tagging ratio, is then  
 162 recorded:

$$R_{absolute}^i = \frac{N_{\gamma \cdot e^i}^{TAC}}{N_e^i} \quad (3)$$

163 where  $N_{\gamma \cdot e^i}^{TAC}$  is the number of photons registered by the TAC in coincidence  
 164 with a particular tagging counter and  $N_e^i$  is the number of counts in the same  
 165 tagging counter. In these normalization measurements, the trigger is set to the  
 166 OR of the tagging counters and  $N_e^i$  is determined by the number of events in  
 167 the self timing peak in its TDC spectrum.

168 Knowing this ratio, one can determine the tagged photon flux in the data  
 169 taking run by counting the number of post bremsstrahlung electrons in the  
 170 tagging counters:

$$N_{\gamma}^{tagged}|_{experiment} = N_e|_{experiment} \times R_{absolute} \quad (4)$$

171 The use of the total absorption counter to calibrate the number of tagged  
 172 photons per electron in the tagger provides an absolute normalization of the  
 173 tagged photon flux incident on the  $\pi^0$  production target. However, these mea-  
 174 surements can be performed only at intervals interspersed throughout the data  
 175 taking. Also in a calibration run, the rate of the total absorption counter is  
 176 limited, and therefore, the tagging ratio can only be measured at a rate which  
 177 is reduced by a factor of about one thousand as compared to the data taking  
 178 run. As such, any rate and time dependence in the tagging ratio must be care-  
 179 fully considered. A pair production luminosity monitor was constructed which  
 180 is able to measure the relative tagged photon flux over a range of all relevant  
 181 intensities, and operate continuously throughout the data taking runs. The pair  
 182 spectrometer (see Fig. 2) uses the physics target as a converter to measure the  
 183 ratio of the number of  $\gamma + A \rightarrow A + e^+ + e^-$  reactions in coincidence with a  
 184 tagging signal to the number of hits in the tagging counters.

185 This enables one to measure a relative tagging ratio:

Figure 2: A schematic layout of the pair spectrometer. Each arm consists of eight contiguous plastic scintillator hodoscopes in each row.

$$R_{relative}^i = \frac{N_{e^+e^-}^{PS \cdot e^i}}{N_e^i} \quad (5)$$

186 where in analogy with Eq. 3,  $N_{e^+e^-}^{PS \cdot e^i}$  is the number of pair spectrometer counts  
 187 in coincidence with a given tagging counter, and  $N_e^i$  is the number of counts in  
 188 a tagging counter. While this is a relative number, its absolute normalization  
 189 can be determined with the TAC.

190 The advantages of the pair spectrometer are that it can operate over the  
 191 entire range of intensities of both the flux calibration with the TAC and the  
 192 production data taking runs, and has a smooth, relatively flat acceptance in  $E_\gamma$   
 193 covering the entire tagging range. The segmentation of the pair spectrometer  
 194 detectors is driven by the fact that the pair production and Primakoff target are  
 195 the same, and therefore the pair spectrometer detectors must accommodate the  
 196 rates from a 5 – 10% radiation length target. Under the *PrimEx* run conditions,  
 197 singles rates on a single telescope were about 140 kHz, and totaled 90 kHz of  
 198 PS-Tagger coincidences over the range of tagging energies. The measured effi-

199 ciency of the pair spectrometer for detecting tagged photons was about 0.5%.  
200 The upstream plastic scintillators were instrumented with Hamamatsu R6427  
201 photomultiplier tubes, while the downstream detectors were coupled to Hama-  
202 matsu R580-17 photomultiplier tubes. Each of the scintillator detector signals  
203 was discriminated with a CAEN N413A non-updating discriminator and tim-  
204 ing information was recorded in a TDC (LeCroy LRS1877). In the analysis, the  
205 electron-positron coincidences were made in software via matching of the timing  
206 signals.

207 To reduce the data acquisition rates, the primary trigger was provided by  
208 the tagged photons in coincidence with the electromagnetic calorimeter. In the  
209 yield, one counts only  $\pi^0$  events which are in prompt coincidence with the tagger.  
210 The  $N_\gamma^{tagged}$  in the denominator of Equation 2 has to be counted consistent with  
211 the way  $Y_{\pi^0}^{tagged}$  is determined. This means that if events are discarded from the  
212 yield calculation, they should not be considered when calculating the photon  
213 flux either, and vice versa. Further, triggering on the calorimeter signal plus  
214 tagger in the production runs as opposed to just the tagger has implications in  
215 the determination of the number of post bremsstrahlung electrons in the tagger.  
216 This will be discussed below.

#### 217 **4. Determination of the absolute tagging ratios**

218 In the calibration runs designed to measure the absolute tagging ratios, the  
219 experimental target was retracted and the Total Absorption Counter (TAC) was  
220 placed in the path of the photon beam 17 meters downstream of the radiator.  
221 This detector consists of a single  $20 \times 20 \times 40 \text{ cm}^3$  lead glass block (SF5, L =  
222 17 r.l.). It has a single 5" attached Hamamatsu photomultiplier tube (R1250,  
223 2.5 nanosecond rise time) and is instrumented with a LeCroy 4413 16 channel  
224 programmable discriminator, a TDC, and an ADC. With a 100 pA electron  
225 beam current and a  $2 \times 10^{-5}$  r.l. bremsstrahlung radiator, it triggered at about  
226 100 kHz with a 35 mV threshold, which corresponds to 0.66 GeV, the energy  
227 threshold used during the *PrimEx* run. To avoid radiation damage to the TAC,

228 the electron beam intensity was typically  $\sim 70 - 80$  pA. Such a low intensity of  
229 the electron beam enables the use of the Tagger Master-OR (MOR) signal as  
230 the data acquisition trigger. The MOR signal is formed by OR-ing the timing  
231 information from all or any of the 11 T-counters. The MOR trigger enables one  
232 to determine the number of electrons that hit a given tagging counter from the  
233 number of counts in its self timing TDC peak.

234 Absolute tagging ratios are then defined for each of the T-counters as in  
235 equation 3. A number of measurements were performed to investigate the ro-  
236 bustness of this procedure and are outlined in the following sections.

## 237 **5. Systematic effects relating to photon flux determination**

### 238 *5.1. Tagger backgrounds*

239 Data taking runs were typically of one to two hours in duration. At the  
240 beginning of each run, photon tagger data was taken for ten seconds with the  
241 beam off. The Master-OR rate (the OR of the 11 T counters used in this ex-  
242 periment) with the beam off was typically a few hundred Hz. For the absolute  
243 calibration measurements with 70-80 pA beam current, the MOR rate was typ-  
244 ically a factor of one thousand higher than this. While this room background is  
245 quite small, these rates were measured without the geometric matching of the E  
246 and T counters. Such a matching gives considerable improvement on top of this  
247 already low background. In addition, an algorithm was implemented to ensure  
248 that data during and around beam trips were not analyzed.

### 249 *5.2. TAC - Tagger coincidence and random background determination*

250 The spectrum of tagger-TAC time differences exhibits a coincidence peak  
251 and a random background. Figure 3 shows a typical coincidence spectrum for  
252 the TAC-Tagger coincidence. Note that the signal to background ratio is better  
253 than 10000 : 1, and thus the determination of the number of prompt coincidences  
254 is quite insensitive to the accuracy of the background estimation procedure.

255 From Fig. 3 one can see that the background is not uniform on either side of  
256 the coincidence peak. In particular, the dip around  $\sim 5$  to 40 ns to the right of

Figure 3: Distribution of time differences for events reconstructed for a single tagging counter and the TAC showing the  $\pm 4.5$  ns timing window for coincidence events.

257 the coincidence peak is due to the TDC dead time. To determine the number  
 258 of TAC-Tagger coincidences, a  $\pm 4.5$  ns window was set up around the peak.  
 259 Because of the nonuniformity of the background, a  $4.5 \mu s$  window, from 7 to  
 260 4500 ns, was taken only on the left side of the coincidence peak to calculate the  
 261 background level, which was taken to be flat and uniform with the introduction  
 262 of negligible error.

### 263 5.3. Effects of incident electron beam intensity on absolute tagging ratios

264 Since the flux calibration and production data taking runs are performed  
 265 under different beam conditions, it is important to demonstrate that the tagging  
 266 ratios obtained at beam intensities of  $\sim 80$  pA are valid when applied to the  
 267 data collected at the high beam intensities of about 80 to 130 nA. One means  
 268 to investigate this involved normalization runs with various beam intensities

269 (40 – 120 pA).

270 No noticeable systematic dependence of tagging ratios on the incident beam  
271 intensity was detected when varying the beam intensity from 40 to 120 pA  
272 and the maximum deviation from the mean tagging ratio for each of the “T”  
273 counters was less than 0.4%. While this study involves only a limited range of  
274 intensities, a more complete answer to the question of intensity dependence of  
275 tagging ratios can be found by looking at relative tagging ratios where the beam  
276 intensity can be changed anywhere from  $< 80\text{pA}$  to  $100 - 150\text{ nA}$ . This will be  
277 discussed later in this paper.

#### 278 5.4. Long and short term reproducibility

279 To test our ability to perform a consistent measurement of the absolute  
280 tagging ratios,  $R_{absolute}$ , back-to-back normalization runs were performed with  
281 the 12.7 mm collimator removed at times 20 to 25 minutes apart. This study  
282 showed that four consecutive runs agree to within less than 0.3%, within the  
283 limits of the required precision and statistical errors.

284 To investigate longer term reproducibility, Fig. 4 (top) shows the results of  
285 absolute tagging ratios measured approximately four and a half hours and five  
286 days apart. Figure 4 (bottom) shows the percent deviation of the tagging ratio  
287 for each T-counter from the relevant average value. The statistical error for each  
288 point is on the order of 0.2%. As seen from the plots, all three measurements  
289 are in very good agreement with each other.

#### 290 5.5. Effects of photon collimator misalignment

291 To study the sensitivity of the tagging ratios on the beam position with  
292 respect to the collimator, measurements for five different collimator positions  
293 were performed and are shown in Figure 5 (top). Figure 5 (bottom) shows  
294 the percent deviation of tagging ratios, measured at different displacements  
295 of the collimator transverse to the beam, from the value which was measured  
296 with the collimator in its nominal centered position (*i.e.*, at  $7.02''$ ). During the  
297 *PrimEx* run, typical measured beam position variations at the photon collimator

298 were less than 0.5 mm. From Figure 5 (bottom) one can see that the shift in  
299 collimator position from 7.02'' to 7.15'' - a 3.3 mm displacement - lowers the  
300 absolute tagging ratios by about 0.34%, indicating a negligible contribution to  
301 the photon flux error budget due small drifts in beam position.

### 302 5.6. Effects of collimator diameter

303 The *PrimEx* experiment ran with very loose collimation of the bremsstrahlung  
304 photon beam to cut out the beam halo and increase the stability of the lumi-  
305 nosity by keeping the photon beam very near to one spot on the target.

306 In Fig. 6 (top) the relative tagging ratios are plotted versus T-counter ID for  
307 data taken with two different collimators. For reference purposes a result with  
308 no collimation is also plotted. Note that for these measurements the statistical  
309 error on each point is on the order of 0.15%. As indicated in Fig. 6 (bottom),  
310 the 12.7 mm diameter collimator cuts out  $\sim 1\%$  of the photon beam and the  
311 8.6 mm diameter collimator cuts out  $\sim 4\%$  of the photon beam.

## 312 6. Normalization of the production data runs

313 As indicated in Eq. 4, a key element in measuring the tagged photon flux  
314 is the counting of the post bremsstrahlung electrons in the tagger. For most  
315 tagged photon experiments at JLab including *PrimEx*, photons are produced at  
316 a rate far greater than is practical for direct counting by the data acquisition  
317 system. The exception to this is the TAC calibration runs where, as mentioned  
318 above, the rates are lower by a factor of one thousand.

319 The traditional technique to measure normalization involves hardware scalers  
320 that are used to count the number of hits in a particular tagging counter. Scalers  
321 have the advantage of being able to count virtually all the hits from a detector.  
322 Also, using scalers to measure the detector rates can automatically account for  
323 beam-trips, *i.e.* uncontrolled beam intensity drops or spikes, provided that the  
324 scalers count signals from a beam related source. However the triggering scheme

325 used for the *PrimEx* experiment makes the hardware scaler method unattrac-  
326 tive exactly due to the fact that scalers would count all the hits in the tagging  
327 counters.

328 The primary trigger for the *PrimEx* experiment was formed by a coincidence  
329 of signals from the electromagnetic calorimeter and the tagger. When the total  
330 energy deposited in the calorimeter exceeded a threshold of 2.4 GeV and there  
331 is a signal available from the tagger, a trigger signal is formed which instructs  
332 the data acquisition system to read out all the channels that have non-zero  
333 information. It is more efficient to use the calorimeter-tagger coincidence as  
334 a primary physics trigger since using the tagger signal alone would flood the  
335 data acquisition due to the high rate of tagging counter signals, most of which  
336 represent photons which just passed through the target without producing an  
337 event of interest. Figure 7 illustrates the basic ideology behind the primary  
338 trigger setup for the *PrimEx* experiment.

339 The *PrimEx* data acquisition system used multi-hit time to digital converters  
340 (LeCroy LRS1877) with a maximum range of 32  $\mu\text{s}$ , double pulse resolution of  
341  $\sim 20$  ns, and with the capability of storing up to 16 hits per trigger event per  
342 channel in a LIFO (Last In First Out) mode. The range of the TDC and the  
343 LIFO limit are programmable and for the *PrimEx* experiment were set to 16  $\mu\text{s}$   
344 and 10 hits, respectively. The capabilities of these TDCs allows for significant  
345 improvement on the analysis techniques of tagged photon experiments described  
346 in Ref. [10].

347 Since only a timing coincidence is required between the calorimeter and  
348 tagger MOR (OR of eleven T-counters) signals to form a trigger, there are  
349 two scenarios for losing prompt  $\pi^0$  - tagger coincidence yield due to the TDC  
350 dead-time (double pulse resolution) and LIFO limit:

- 351 1. An entire event is lost due to TDC dead-time, *i.e.*, there was no signal  
352 from tagging counters to form a prompt coincidence with the calorimeter  
353 signal but the data acquisition system is ready to take data. From the  
354 stand point of photon flux determination, this case is very similar to the

355 situation where the data acquisition system is busy reading out data and  
356 is not accepting any triggers.

357 2. A photon producing a  $\pi^0$  may be lost due to the LIFO limit but the  
358 triggering condition might be satisfied by a signal from another tagging  
359 counter. Just like in the previous case such events will not contribute to  
360 the tagged yield.

361 To measure a cross section, one is interested in the number of tagged photons  
362 on the target which have the potential to produce a prompt coincidence between  
363 the tagger and the photo-induced event of interest, which in this case is a  $\pi^0$   
364 in the HYCAL calorimeter. While the yield of  $\pi^0$  - tagger prompt coincidences  
365 is reduced by the TDC intrinsic dead-time, LIFO limit and the DAQ readout  
366 dead-time, below (in sections 6.1 and 6.2) we describe a method for determining  
367 the photon flux which is affected in the same manner as the  $\pi^0$  - tagger prompt  
368 coincidence yield. This obviates the need to correct for the number of the tagged  
369 photons lost due to these effects.

370 The rate of tagged photons can be determined from the timing information,  
371 recorded by tagging counters, via sampling of the number of hits for a small  
372 fraction of the time. An assumption is then made that these samples are repre-  
373 sentative of the detectors' rates for the times when no data are recorded. This  
374 can be used to extrapolate to all times in order to determine the total number  
375 of tagged photons represented by a given data sample. Since one is interested  
376 in the number of tagged photons that have the potential to produce a prompt  
377  $\pi^0$  - tagger coincidence, the timing information from only fully reconstructed  
378 hits in the tagger needs to be considered. A fully reconstructed hit requires a  
379 hardware timing coincidence between the PMTs fitted to each of the ends of  
380 a T-counter that is simultaneously in time with a hit in an E-counter. The  
381 coincidences between "E-" and "T-" counters are also subject to a geometric  
382 matching where the two counters are required to be on an electron trajectory  
383 which is consistent with the magnetic optics of the tagger.

384 The LeCroy 1877 TDCs with which the T-counters were equipped oper-

385 ated in common stop mode during the *PrimEx* experiment. A T-counter signal  
386 passed through a constant fraction discriminator and was split into two signals.  
387 One signal started the TDC and the other signal passed through an E-T co-  
388 incidence/MOR module. Assuming a coincidence between the left and right  
389 T-counter PMTs, the MOR module sent a signal to the trigger supervisor when  
390 any E-T coincidence was obtained. If a signal from the calorimeter was in co-  
391 incidence with the MOR signal, the trigger supervisor issued a common stop  
392 trigger signal to all electronics involved in the data acquisition. Figure 8 shows  
393 an example of a timing spectrum of hits reconstructed for a single T-counter in  
394 the tagger. Note that the abscissa in Fig. 8 (*top*) is presented on a log scale. The  
395 peak in the timing spectrum at around 100 ns corresponds to the time difference  
396 between the two split signals from a single T-counter, *i.e.*, is associated with  
397 the events when this particular T-counter was involved in the trigger. The flat  
398 accidental background comes from signals that were not involved in the trigger  
399 but were accidental hits recorded due to the common stop/multihit nature of  
400 T-counter TDCs.

401 One obvious effect seen in Figure 8 (*bottom*) is that the number of hits trails  
402 off on the right side of the spectrum due to the LIFO limit. Since during the  
403 *PrimEx* experiment the LeCroy 1877's were used in a common stop mode, earlier  
404 times are to the right and later times are to the left in this plot. The LeCroy  
405 1877 TDC will always report the latest hits. Thus when the LIFO buffer fills  
406 up, the earlier hits are overwritten by later ones.

#### 407 6.1. The “out of time” method

408 The tagged photon flux at the target can be determined by means of sampling  
409 the “out-of-time” (OOT) electron hits in the tagger T-counters. The term  
410 “out-of-time” electron refers to any fully reconstructed electron which was not  
411 involved in the formation of the trigger signal. The idea is to simply count the  
412 number of hits in a particular T-counter within some user defined time window  
413  $w$  and divide by the size of the time window. Since even high rate detectors on  
414 average tend to have only a few hits per event, it is necessary to integrate over

415 many events to obtain an accurate value for the rate.

416       When counting hits, it is important to discard those that could be associated  
417 with the trigger. Hits which are correlated with the trigger are biased and will  
418 artificially increase the calculated rate. The OOT window,  $w$ , should be defined  
419 in such a manner that it does not include the trigger coincidence peak region  
420 but can include areas both before and after the trigger peak. One drawback of  
421 this rate sampling technique is that it is potentially vulnerable to beam intensity  
422 variations since it will tend to sample more often when the beam intensity is  
423 higher. As such, the “clock trigger” method was implemented as described  
424 below.

#### 425 *6.2. The “clock trigger” method*

426       To ensure that the calculated rates are not biased by beam intensity vari-  
427 ations, a 195 kHz clock trigger, which was completely uncorrelated with the  
428 electron beam current, was implemented in addition to the physics trigger. The  
429 clock triggers were pre-scaled so that the data are dominated by events of physics  
430 type that are of interest. The pre-scale factor depends on the electron beam  
431 intensity and on the type of the data taking run, *i.e.*, pion photoproduction,  
432 or calibration runs involving Compton scattering or pair production. Figure 9  
433 shows a sample timing distribution for hits reconstructed in a single T-counter  
434 recorded with the clock trigger. As in the case of the tagger MOR-calorimeter  
435 coincidence trigger, one can see a depletion of hits due to the LIFO limit starting  
436 at around  $10\mu\text{s}$ , but the peak characteristic of a beam related trigger is missing.

437       The same out of time window,  $w$ , shown in Figure 9, is used when calculating  
438 the rates with either clock or physics triggers. It was chosen to be  $7\mu\text{s}$  for all  
439 T-counters spanning from 500 to 7500 ns, thus avoiding the coincidence peak in  
440 the case of MOR-calorimeter coincidence trigger and the region affected by the  
441 LIFO limit for both triggers. Extra effort has been put into checking that the  
442 distribution of hits inside the out of time window is flat.

443       Following the above described procedure for an electron rate calculation we  
444 have:

$$r^i = \frac{n_e^i}{w \cdot n_{trigger}} \quad (6)$$

445 where  $r^i$  is the rate of T-counter  $i$ ,  $n_e^i$  is the number of hits within the out of  
 446 time window of width  $w$  and  $n_{trigger}$  is the number of times the T-counter  $i$   
 447 could have had a hit, *i.e.*, the number of triggers. Equation 6 assumes Poisson  
 448 statistics for “out of time” electrons and it assumes constant electron rate per  
 449 T-counter.

450 The *PrimEx* experiment utilized a second generation of the JLab designed  
 451 Trigger Supervisor (TS) module. This module is designed specifically to op-  
 452 timize event rates for Fastbus and VME based data acquisition systems like  
 453 those commonly used in intermediate and high energy physics experiments.  
 454 One new feature in the second generation model is the inclusion of two scalers  
 455 dedicated to measure the live-time of the DAQ. Both scalers are driven by a  
 456  $195.3160 \pm 0.0045$  kHz internal clock. One of these scalers is live-time gated while  
 457 the other is free-running. The ratio of the two gives the fractional live-time of  
 458 the data acquisition system.

459 To determine the tagged photon flux, one needs to know the number of the  
 460 hits in a detector during the live-time of the data sample. This can be obtained  
 461 using only the live-time gated scaler to calculate the actual live-time as shown  
 462 below. Note that the free running scaler is not needed since both the  $\pi^0$  yield  
 463 and the photon flux are affected by the data acquisition system dead time in  
 464 the same way:

$$T_{live} = n_{gated} \cdot \beta \quad (7)$$

465 where  $n_{gated}$  is the number of scaler counts from the gated TS scaler and  $\beta =$   
 466  $\frac{1}{clock\ frequency}$ , *i.e.*,  $\beta = 5119.9083 \pm 0.0002$  ns.

467 The *PrimEx* data acquisition system had the option of a variety of triggers  
 468 which could be prescaled as needed. In this case, it was a prescaled 195 kHz  
 469 clock. When this clock was responsible for the event trigger, a bit was set  
 470 indicating it was a clock trigger. The number of such triggers could thereby be

471 tallied in the off line analysis. Given Equation 7, the total number of electrons  
 472 counted by T-counter  $i$  during the time the data acquisition was live is expressed  
 473 by:

$$N_e^i = r^i \cdot T_{live} = \frac{n_e^i}{w \cdot n_{trigger}} \cdot n_{gated} \cdot \beta \quad (8)$$

474 The number of tagged photons  $N_\gamma^i$  in T-channel  $i$  which can reach the physics  
 475 target can be calculated as:

$$N_\gamma^i = N_e^i \cdot R_{absolute}^i \quad (9)$$

476 where  $N_e^i$  is the number of counts per T-channel  $i$  and  $R_{absolute}^i$  is the tagging  
 477 ratio, which is determined in the TAC analysis.

478 The value of the window width  $w$  was obtained using the TDC conversion  
 479 factor specified by the manufacturer. As the total rms error is 400 psec, the in-  
 480 tegral non-linearity is less the 25 ppm full scale, the full scale error is  $\pm 0.0025\%$ ,  
 481 and the long term stability is less than 100 ppm/year[11], the uncertainty in  $w$   
 482 is negligible.

## 483 7. Relative photon flux normalization with pair production

484 The pair spectrometer is designed for relative in-situ monitoring of the pho-  
 485 ton flux and is an essential part of the *PrimEx* experimental set up. It uses  
 486 the physics target to convert a fraction of the photons into  $e^+e^-$  pairs which  
 487 are deflected in the field of a dipole magnet downstream of the target and are  
 488 registered in plastic scintillator detectors on both sides of the beam line. The  
 489 relative tagging ratio for a given T-counter is given by Eq. 5.

490 During the *PrimEx* production data taking, electron-positron pairs in coinci-  
 491 dence with the clock trigger were measured to determine  $R_{relative}^i$ . As with the  
 492 physics triggers of interest, the clock trigger also enabled a direct count of the  
 493 number of electrons detected by the tagging counters for the determination of  
 494  $R_{relative}^i$ , with the advantage of being insensitive to beam intensity variations.

495 *7.1. PS-tagger coincidence window and background*

496 The events reconstructed in both the tagger and the pair spectrometer are  
497 randomly distributed in time with respect to the clock trigger. The spectrum of  
498 tagger - pair spectrometer time differences exhibits a prompt coincidence peak  
499 and a random background. A sample timing spectrum is shown in Fig. 10.

500 In general, taking the difference of two random distributions, defined over  
501 the same interval, results in a triangular shape distribution. This provides an  
502 exact background model, which enables one to easily simulate the “background  
503 only” part of the spectrum.

504 *7.2. Effect of incident electron beam intensity on relative tagging ratios*

505 In order to justify the use of the absolute normalization of the photon flux  
506 obtained at the low electron beam currents of the TAC runs for the calculation  
507 of the number of tagged photons on target, it is important to demonstrate the  
508 independence of the  $R_{relative}^i$  on the electron beam current. The relative tagging  
509 ratios, defined by Eq. 5, provide valuable confirmation of this procedure as they  
510 can be measured at the low currents of the TAC runs as well as at high electron  
511 beam currents of the production data taking runs.

512  $R_{rel}^i$  was measured for electron beam currents ranging from 0.08 to 100 nA.  
513 The results for a representative T-counter are shown in Figure 11, where the  
514 percent deviation from the mean value for this T counter is indicated for each  
515 individual intensity. For these measurements of the rate dependence of the  
516 relative tagging ratios, a tagger Master-OR trigger was used. Figure 12 shows  
517 the percent deviation from the mean of the measured  $R_{rel}$  as a function of  
518 beam current integrated over the full photon tagging energy range (*i.e.*, treating  
519 tagging counters T1-T11 as one single counter) where it can be seen that the  
520 variation is at the  $\pm 1\%$  level.

521 *7.3. Stability of relative tagging ratios*

522 The relative tagging ratios have to be not only intensity independent but also  
523 stable from run to run, *i.e.*, in time, to within 1%. The time stability of the

524 relative tagging ratios measured by the pair spectrometer justifies the use of a  
 525 single set of absolute tagging ratios measured by the TAC for the tagged photon  
 526 flux calculation. As such, to achieve a 1% level tagged photon flux measurement  
 527 integrated over the tagged photon energy range, any deviation from the nominal  
 528 value of the  $R_{relative}$  has to be carefully investigated and if possible corrected.  
 529 In the discussion that follows, the data from eleven T-counters were combined  
 530 together and the part of the focal plane of the tagger that is of interest to the  
 531 *PrimEx* experiment is treated as one single counter, thus enabling a reduction  
 532 in the statistical error.

533 Fig. 13 shows the time dependence of  $R_{relative}^{combined}$  - the combined relative  
 534 tagging ratio for data taken with a carbon target. The two black solid lines  
 535 on the graph represent a  $\pm 1\%$  deviation from the weighted average for run  
 536 numbers less than 4800. One can see that for the last group of runs (run  
 537 number  $> 5150$ ), the relative tagging ratio falls off. This deviation, which was  
 538 found to be associated with high current beam delivery to experimental Halls A  
 539 and C at Jefferson Laboratory, is larger than 1% and indicates that a correction  
 540 is needed when calculating the photon flux for this group of runs.

541 The change in  $R_{relative}^{combined}$  in Fig. 13 can arise from the tagger registering  
 542 extra electrons which do not produce photons, or a part of the photon beam  
 543 being lost before reaching the physics target (or TAC, since the same effect has  
 544 been seen in absolute tagging ratios), or both. In either case, the measurement  
 545 of the relative tagging ratios enables a correction to be made to compensate for  
 546 these changes in experimental conditions on a run-by-run basis.

547 The pair spectrometer also provides information on the performance of the  
 548 photon tagger. Fig. 14 shows a  $\sim 3.5\%$  drop in the fraction of the photons  
 549 on the target which are tagged by tagging counters T1 through T11,  $\frac{N_{e^+e^-}^{PS}}{N_{e^+e^-}^{PS}}$ ,  
 550 when going from the 80 nA (runs 4747 - 4768) to the 130 nAmp (runs 5158-  
 551 5210) groups of runs. This overall drop can be explained by a drop in the  
 552 absolute efficiency (hardware and reconstruction) of the tagging counters with  
 553 an increase of the beam current.

554 In Fig. 15 is plotted the ratio of the number of  $e^+e^-$  pairs registered in the

555 pair spectrometer to the number of electrons registered in the tagger. The plot  
556 shows a  $\sim 3.2\%$  rise when going from the 80 nA group of runs to the 130 nA  
557 group, which again can be explained by inefficiency of the tagger at high beam  
558 intensities.

559 A strength of the photon tagging technique is, of course, the fact that the  
560 absolute efficiencies of the photon tagging detectors need not be known in the  
561 photon flux determination. Such investigations of efficiencies, however, can be  
562 of relevance in determining the optimal beam current at which to run a given  
563 experiment.

## 564 **8. Conclusions**

565 Using the techniques described here, the Jefferson Laboratory *PrimEx* Col-  
566 laboration has performed a high precision measurement of the neutral pion  
567 lifetime whereby an accuracy at the 1% level in the tagged photon flux inte-  
568 grated over the tagging energy range was achieved. Major elements include the  
569 implementation of multi-hit time to digital converters, electron counting tech-  
570 niques involving sampling of the post bremsstrahlung electron rates, and the  
571 implementation of a pair spectrometer for continuous, on-line measurement of  
572 relative tagging ratios. While this discussion has been in the context of a mea-  
573 surement of the photoproduction of neutral pions, many of these techniques are  
574 applicable to other high precision photon tagging experiments.
